REDUCTION OF DISLOCATIONS OF THE SHOULDER.—The number of modes of reducing dislocations of the shoulder shows that the best plan is yet generally unknown. A valuable paper on this subject was read by M. KOCHER at the meeting of the International Congress in London. Referring only to the subcoracoid form of dislocation, he asserts that the aim of the surgeon should be to open out the rent in the capsule, and to relax the parts of the capsule which are untorn but tightly stretched by the false position of the head of the humerus. The rent in the capsule is on the inner side of it; the most tense part is in the upper portion, where it is thickened by the coraco-humeral band; the lower part of the capsule is also tense. Kocher asserts that by rotating the arm outwards the top of the capsule is itself rotated out and the rent rendered patent. If now the arm be advanced in the vertical median plane, the upper part of the capsule is relaxed, and the head of the bone, being prevented passing forwards by the lower fibres of the capsule, enters the glenoid fossa. He accordingly directs that for the reduction of this dislocation the following manipulation should be practised. The patient should be seated, with the surgeon on his left hand. The elbow-joint is first to be flexed to a right-angle, and the joint firmly pressed against the side of the chest; then while holding the elbow in contact with the body the arm is to be slowly, gently, and steadily rotated out until firm resistance is encountered; then maintaining this rotation the arm is to be raised forwards and a little in, and lastly to be rotated in and the hand brought towards the opposite shoulder. It is stated that there is no need for anæsthetics when this manipulation is employed. This method, which has great advantages over those in common use in this country, is stated by M. Ceppi (*Revue de Chirurgie*) to be especially valuable in old dislocations, enabling them to be reduced often without any force and without anæsthetics. M. Kocher has succeeded in twelve cases of dislocations, varying from three weeks to four months old. In one case, where the bone had been displaced for eight weeks, he fractured the shaft of the humerus in attempting the reduction, and six weeks later, when the bone was united, failed again. The patient was seventy years of age. We believe that this method of reduction is worthy of far more attention than it has yet received.—*Lancet*, November 4, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, NOVEMBER 25, 1882.

THE LEGAL RELATIONS OF PHYSICIANS AND THE CORONER.

TIME was when the coroner's inquests were numbered by the score: now it is by the hundred, and threatens soon to be by the thousand. The coroner's claims have gradually been extended to cover large classes of cases never contemplated by the law, until there are few citizens who have escaped disagreeable contact with his office, and the public treasury is depleted at least by additional expenses if not by additional salary. We are glad to see that the Supreme Court of Pennsylvania has lately decided a case so clearly that its result must be to restrict coroners in this State within their just limits.

Mishler, the Coroner of Lancaster County, sued the County to recover fees for an inquest in a case of death from "a paralytical stroke." The Supreme Court held that where there is "no ground for suspecting that the death was not a natural one, it is a perversion of the whole spirit of the law to compel the county to pay him for such services," and he is not to be paid.

The only object of a coroner's inquest in any case is here indicated, viz., when death is presumably *not from natural causes*, but from accident, poisons, or other unnatural causes, the coroner investigates the case with a view to determine whether any person is responsible for the death, and if so, to take the necessary steps to bring him to justice.

There is so much ill-defined knowledge of the law as it exists in Pennsylvania, and especially in Philadelphia, that it will be well to examine it and state it clearly for the information of the profession.

In order to understand exactly what the law is, let us quote it from the *Medical Register*, page 279: "It shall be the duty of the coroner of the city and county of Philadelphia, to hold an inquest on the body of any deceased person who shall have died of violent death, or whose death shall be sudden; *provided* that such sudden death be after an illness of less than twenty-four hours, and that no regular practising physician shall have been in attendance within said time, or that suspicious circumstances shall render the same necessary, which said suspicions shall first be sworn to by one or more citizens of said city."

There are therefore three classes of cases in which it is both the right and the duty of the coroner to hold an inquest. First, in all cases of certain violence. Yet we have known his right to be contested and a physician to give a certificate in a case of death from burn, and again, not long since, in a case of death after a fracture of the thigh from a fall—both clearly encroachments on the rights of the coroner to the disadvantage of the community. For in *all* cases of death by violence (which includes murders, suicides, accidents, poisonings, etc.) the fact as to whether any person was responsible for the violence must be established by a judicial investigation, *i. e.*, by the coroner.

Secondly, cases in which though violence is not certain, yet there are suspicious circumstances about them. But these suspicions must be sworn to by at least one citizen before the coroner dare interfere.

The third class, however, is the one about which there is the chief misapprehension. It is a very wide-spread opinion that the law requires the coroner to be informed, and to hold an inquest, in every case in which the physician has been attending for less than twenty-four hours before death. This is not the case. The exact requirement of the law is twofold: first, that the *sickness* has been of *less* than twenty-four hours duration; and, secondly, that *no* physician has been in attendance within said time. If, in any case of sudden illness of less than twenty-four hours' duration, a physician *has* been in attendance, at *any time* before death, no matter how short that time be, it is not only his right, but his duty, to give a certificate, unless, of course, the case should belong to either of the classes previously described.

Cases of sudden death after an illness of *more* than twenty-four hours' duration, do not come under the jurisdiction of the coroner, whether any physician has been in attendance or not.

And the word "attendance" is evidently not to be construed to mean an actual visit to or by the patient within the last twenty-four hours before death. Dr. Walter F. Atlee's case, a year ago, is in point. A patient with valvular disease of the heart, who came

to his office once in a week or so, suddenly died. Dr. Atlee very properly gave a certificate. But we are informed that the coroner actually exhumed the body without the knowledge of the dead man's relatives, made a *post-mortem* examination and held an inquest, all in clear violation of the law, unless there were suspicions sworn to before the coroner. At the inquest he also formally fined Dr. Atlee $25 for giving the certificate. We do not believe that there is any law authorizing such a fine, even if Dr. Atlee had done wrong, and we do know that Dr. Atlee defied the coroner to collect the fine, and he has never dared to attempt it. Sudden death is, indeed, to have an added horror, if in every case in which a physician has not actually seen the patient for twenty-four hours before death, and in which not the slightest suspicion of any violence or wrong exists, a body more precious to us than gold, is to be given over to the rude handling of strangers, a repulsive legal *post-mortem* examination is to be made, the house of mourning to be ruthlessly invaded, and the heart-stricken relatives, while awaiting the funeral, to be forced to appear amid the unsavory crowd about the coroner's office, and the facts to be blazoned abroad in the public press! Most certainly in this case the coroner exceeded his functions. All of us have patients whom we only see once in a week, a month, or even three or six months; as, for instance, cases of infrequent epileptic fits, chronic Bright's disease, Potts's disease, paralysis, slow spinal disease, heart diseases, in nearly all of which sudden death may, and often does, occur, and in which a certificate of death it is not only our right, but our duty, to give, if it be the result of the already existing disease. If, however, it be from an intercurrent disease then the case must be decided upon its merits, independently of the chronic disease.

The law of March 8, 1860, section 3 (*Medical Register*, page 274), requires "that whenever any person shall die in the city of Philadelphia, it shall be the duty of the physician who attended during his or her last sickness, or of the coroner when the case comes under his notice, to furnish within forty-eight hours after the death . . a certificate setting forth, as far as the same can be ascertained, the full name, sex, color, age, and condition (whether married or single) of the person deceased, and the cause and date of death," and section 5 fines him five dollars for either refusal or neglect to do so.

But suppose the physician, called, it may be a short time before death, is not certain of the cause of death, what shall he do? We take it that if no violence has occurred, and no suspicious circumstances require its being reported to the coroner, that it is the right and the duty of the physician to give a certificate stating the cause of death, in the words of the law just quoted, "so far as the same can be ascertained." If there be no violence and nothing suspicious about the death, society does not care a button as to whether it was this or that disease. It is purely a scientific question. The doctor, therefore, should request a post-mortem examination, and in nearly all cases upon proper explanation this would be accorded, and would clearly reveal the cause of death. Where it is refused he should report that fact with all other necessary information to the Health Officer. But if there be the slightest suspicion of wrong, he should report it to the coroner. But according to the strict letter of the law, we do not see that the coroner could take charge of the case, unless the suspicion were sworn to. That, however, concerns him and not the doctor.

But suppose *no* physician has been in attendance during the last illness, may a physician called after death give a certificate? Clearly not, though we have heard of its being done. What then is proper? Who will give the necessary certificate? If the illness has been of less than twenty-four hours duration the coroner must be notified, and he must hold an inquest, and if need be have a *post-mortem*, and he will furnish the certificate. If the illness has been for more than twenty-four hours (and there is no violence or suspicion of wrong-doing), it does *not* come under the coroner's jurisdiction, but the law of 1860, section 4 (*Medical Register*, page 275), specially provides that "in case any person shall die without the attendance of a physician, or if the physician who did attend at the time of the death refuses or neglects to furnish a certificate as aforesaid, it shall be the duty of the undertaker, or of any other person acquainted with the facts to report the same to the Health Officer, who shall be authorized to give a certificate of death as aforesaid, provided it be not a case for the attendance of the coroner," which last we have shown is not the case.

Very many of the inquests by the coroner of this city are held without any warrant of law. Especially is this the case in our hospitals. No matter what the duration of the illness in a hospital patient, as a physician is in attendance in every case, the coroner has no right to make a *post-mortem* or to hold an inquest, except where the death results from violence or there are suspicious circumstances which are sworn to.

We have quoted the law from the *Register* as it is more accessible to the profession, and by a comparison with West's Digest we have ascertained its correctness.

"THE GOSPEL OF RELAXATION."

HERBERT SPENCER never lacks an audience. His criticisms on us as a people are both timely and in

the main just; and they have been read with both interest and profit. In his recent after-dinner speech, or homily, as he called it, he has taken us to task for our overwork, and our early gray hairs; but withal, it seems to us that he missed one clear distinction which it is of the utmost importance to bear in mind—a distinction which his countryman and our distinguished *confrère*, Mr. Seymour Haden, however, has not forgotten, and of which physicians are, in an eminent sense, the best judges —namely, the distinction between *worry* and *work*. Indeed, Mr. Spencer himself is a conspicuous example of the truth that even a feeble man, physically, if he will work wisely and in a way to avoid great friction, may accomplish even herculean tasks.

We do not believe that work alone, even when fairly prolonged and severe, frequently shortens life. It is rather the worry that too often goes hand-in-hand with it. Our furious methods of work, our intense excitement, these are the evils that are to be deprecated above all others. Of course, we assent to Emerson's doctrine that a man must first of all be "a good animal." We say Amen! to the preaching of the "gospel of relaxation," as well as to the scriptural maxim, to learn of the ant. Monotonous daily toil will furrow the face, and make the healthy, hearty child prematurely old. Intense application to business breaks down many a merchant. Black Fridays will kill or maim many a stock-broker and speculator, whether in grain, or cotton, or stocks. But what does all this mean? A struggle for bread, an intense strain on the nervous system, a heedless, headstrong hurry to be rich. The mast that will endure a steady gale will snap and go by the board after oft-repeated sudden flaws.

We doctors see this only too often in our patients, and not a few of us exemplify it in our own lives. When work becomes a "passion," as Mr. Spencer points out is too often the case on this side of the Atlantic, it ceases to be work pure and simple. It is accompanied by great anxiety and by heavy responsibilities. Thousands of dollars, it may be one's whole fortune, are at stake; meals are hurriedly eaten, or are not eaten at all; the hours properly claimed by relaxation and recreation are given up to planning for the morrow's business; even the hours of sleep are curtailed; and such high-pressure work, such worry and friction, soon tell on the physical health. Digestion is impaired; sleep will not be woed even by weary eyelids; the worried brain, never rested from its anxious cares, at last gives out, and the hale man of yesterday is to-day a wreck. None has more clearly or forcibly shown these evils in their true proportions than Dr. H. C. Wood in his primer on *Brain Work and Overwork*. The physician is also liable to be a victim of such unwise methods of work. The very nature of his profession involves great worry. The larger his practice, the larger the number of his serious and important cases. Men of influence and large business, women of social and family distinction, lying at the point of death, tax his skill to the utmost, and weigh him down with care. Disease will not brook any "thus far and no farther," but encroaches on his hours of sleep, of meals, and of recreation; and he, too, follows his patients to sickness, and sometimes to the grave.

Moreover, these evils are often exaggerated and reinforced by the vicious means employed to stay the evil, or to gratify the passions. Excessive use of stimulants and narcotics, such as alcohol, tobacco, coffee, and the like, often provide a temporary relief, only to be followed by greater subsequent depression, and surer disaster.

But we believe a brighter day is dawning. As society accumulates wealth it is more apt to take its ease. The London Stock Exchange, or the Paris Bourse, is very much like that of New York or Philadelphia, but, as a rule, Englishmen take life much more easily than we do. The east and the west in this country, while alike greedy of gain, differ materially in their methods of living as a people. The tone of society changes perceptibly the further one goes west of the Alleghanies. Moreover, our people are learning the value of the summer holiday. Of course there are men who make Long Branch and Saratoga a part of Wall Street, but the population as a whole take far more and far longer holidays than they did twenty years ago. Who but nabobs then had seaside or country houses to which they took their families for weeks and months? What business man a score of years ago claimed more than a week or ten days as his own? What stores closed at 5 P. M., and on Saturdays at 3, or even at 1 o'clock, in July and August, till within a decade?

Rest and relaxation are steadily growing in favor, and so diminishing friction; and while business men are building larger establishments than ever before, yet they are wise enough to hire skilled labor to take responsibility as well as to do manual work.

CIRRHOSIS OF THE LIVER.

IN a recent lecture on cirrhosis, LANCEREAUX recognizes several forms: the syphilitic, the malarial, the alcoholic. In that form of the disease due to syphilis, the liver is deeply lobulated, furrowed, and adherent by strong fibrous bands to the neighboring organs. The connective-tissue formation which divides the different parts of the parenchyma grows thicker towards the periphery, and the cellular hyperplasia is especially abundant about the lymphatic

and arterial systems. Ascites rarely occurs, and when present is readily cured. There is neither dilatation of the veins nor icterus, unless, indeed, the new formations compress the biliary ducts.

The malarial liver has a considerable size; its consistence is firm, and its surface presents a granular appearance, but less so than the alcoholic liver. The color recalls the appearance of granite or porphyry. The hyperplasia of the connective tissue, both inter- and intra-lobular, preserves the embryonic character, and the gland-cells contain numerous pigment granules. The principal clinical characteristics of these cases are increase in the volume of the liver and of the spleen, long-standing icterus, and slow development without pronounced symptoms.

Alcoholic cirrhosis presents itself under two forms. 1. The liver increased in size, the surface glazed or tanned, and presenting a hyperplasia of the connective tissue, both inter- and intra-lobular, with granular and fatty degeneration of the gland-cells. 2. Contracted, hard, fibrous, and marked by granulations of considerable size, generally distributed throughout the organ.

The diagnosis in the alcoholic form rests on the considerable emaciation of the patient, the dryness of the skin, the enlargement of the abdomen due to the accumulation of fluid, and the increasing dilatation of the veins of the abdominal wall. Death is usually due to mechanical interference with respiration. In the syphilitic form the liver, by reason of its volume, resembles the condition due to malarial poisoning, and ascites is equally wanting. Although jaundice is a protracted symptom in the malarial liver, it is a concluding symptom in cirrhosis of alcoholic causation.

THE DIAGNOSIS OF UNILATERAL RENAL DISEASE.

IN our issues for March 4th and 11th we considered the question of renal operations at some length, and recognized the fact that there was great difficulty in some cases of deciding on which side the disease existed, and whether the opposite kidney was sufficiently active to justify the removal of the diseased one. Glück has lately proposed what is at least an ingenious method of deciding this question, which doubtlessly will be tested before long and its value determined. He proposes, after exposing the presumably diseased kidney through a small wound, to secure the ureter by a temporary clamp or ligature; if a double ureter exist, both tubes must be closed. A solution of ferrocyanide or iodide of potassium, or some other rapidly eliminated salt, is then to be injected subcutaneously and the urine tested in a few minutes. If no evidence of the salt appears in the urine, the presumption is against the normal condition of the opposite kidney, and the operation should be abandoned. Of course a single, horse-shoe kidney could not be diagnosticated, and the proposed exploration might prove to be so difficult as to be unjustifiable; but in ordinary cases of doubt, the suggestion is at least deserving of consideration.

PRECAUTIONS AGAINST CONTAGIOUS-DISEASES.

SOME months ago we adverted to the want of legal provision to prevent the spreading of contagious diseases by funerals, hacks, etc., and we are glad to see that the Philadelphia City Council's Committee on Law, at the instance of the Board of Health, have agreed to report an efficient bill which may well serve in most respects as a model to other cities that have none. As the matter is of such great importance and wide application, we note briefly its provisions.

Any person sick with a contagious disease using any public conveyance without previous notification to the driver, is to be fined $25 and to recoup the driver for all consequent expenses and losses. Public funerals in the case of death from a contagious disease are prohibited under a penalty of $50, and the person authorizing the notice of the death must publish the cause of death under a penalty of $10. Persons letting houses or rooms without being thoroughly disinfected, which have been occupied by patients sick of such diseases, are liable to a fine of $100, and any person who exposes himself, or any attendant who allows him to expose himself without proper precaution in the public streets or conveyances, or any one who similarly exposes bedding, clothing, rags, etc., which may thus spread disease, is to be fined $25.

One most serious and fertile source of contagion unfortunately has been forgotten. There should be a penalty inflicted on parents who send their well children to public schools while cases of scarlet fever, measles, smallpox, or varioloid exist at home. Careful parents under competent medical guidance might often do so without harm; but it would scarcely do even to trust to a doctor's certificate that the circumstances would render it safe, for the doctor is often ignorant of what relaxation of his rules exists when he is absent, or he may be too good-natured, or anxious not to offend by a refusal. So many of the public school children come from houses in which the physical conditions are such that proper isolation cannot possibly be had, that the rule of exclusion must be absolute or it will be worthless.

We commend the bill, and trust that in enacting it into a law the amendment we propose will not be overlooked.

IT is so rare that an Englishman sees anything to praise in this country, that we are surprised to find

the Waverly Convalescent Home warmly commended in a letter published in a recent number of the *Lancet*.

This home is said by the correspondent to be very complete; "indeed," he says, "I have never seen a more model institution than the Waverly Convalescent Home." As some of our readers may not be acquainted with this home which excites the enthusiasm of a "roving correspondent" from England, we venture to explain that it is the convalescent house of the Massachusetts General Hospital. It owes its existence chiefly to the philanthropic labors of Miss Russell, and is devoted to the reception of the *convalescent poor* from the hospital, pay patients being excluded. It is situated at Waverly, seven miles from Boston. It is truly a "model institution," as described by the *Lancet* correspondent, and in this case all the praise bestowed is well deserved. It were well, if all our great public hospitals were provided with "homes" in the country to which their convalescents could be sent, to more effectively recuperate than is possible under the sanitary conditions usually surrounding this class of subjects in our cities.

WE have the pleasure, through the courtesy of Col. Seaton, of laying before the profession a *résumé* of the mortality statistics of the United States which have been collected by the United States Census Bureau, in accordance with plans and forms prepared by Surgeon John S. Billings, U. S. A. These statistics are particularly valuable, since they furnish us for the first time with reliable information as to the death-rate of the whole country, which, it is gratifying to find, compares favorably with that of other civilized countries.

SPECIAL ARTICLE.

MORTALITY STATISTICS OF THE UNITED STATES.

THE Compendium of the 10th Census which is now nearly through the press, and will probably be ready for issue by the time Congress meets, is a very interesting document to statisticians, not only for what it contains, but for the glimpse which it gives of what may be expected in the full quarto reports.

Through the courtesy of Col. Seaton, we are able to give our readers so much of the text of the Compendium regarding the mortality statistics as is of special interest to physicians, independent of the tables which belong with it.

The total number of deaths recorded and tabulated as occurring in the United States during the census year is 756,893, being a death-rate of 15.1 to the thousand. This death-rate is decidedly higher than that given in the census of 1860, viz., 12.5, and of 1870, viz., 12.8 per thousand, but this does not indicate any actual increase in the number of deaths as compared with the living population. It shows, rather, that the efforts made in the census of 1880 to obtain more complete returns of deaths than had been collected in previous enumerations have been to some extent successful.

Excluding the States of Massachusetts, and New Jersey, and also the following named cities: Baltimore, Bangor, Brooklyn, Chicago, Cincinnati, Charleston, Cleveland, Indianapolis, Louisville, Milwaukee, Mobile, Nashville, New Orleans, New York, Philadelphia, Pittsburg, Providence, Richmond, St. Louis, San Francisco, and Wilmington, the number of deaths actually reported by the enumerators was 520,339. To these returns of deaths furnished by the enumerators, there were added from registers furnished by physicians throughout the country, 61,020 additional cases of death. For the States of Massachusetts and New Jersey, and the cities above mentioned, the State and municipal registration records of deaths were copied and used in the tabulations. These records are based on a regular system of registration, and on burial permits, and are therefore probably very nearly accurate. The records give 175,534 deaths.

In order to obtain some positive data from which might be calculated the amount of deficiency in the enumerators' returns of deaths, their returns for the State of Massachusetts, excluding the city of Boston, and for the whole State of New Jersey, have been tabulated and compared with the records furnished from the State registration office, the total deficiency in which is considered not to exceed 2 per cent. The result of this comparison is, that for the State of Massachusetts, excluding Boston, the deficiency in the enumerators' returns amounts to 26.42 per cent. of the whole number returned by them. For the State of New Jersey, the deficiency is 34.45 per cent. It may be considered certain that in no State is the deficiency in the enumerators' returns less than it is in Massachusetts.

The deficiency is greatest in the case of infants, of females, and of foreigners, and increases in a tolerably uniform ratio for each month going backwards in time from the date of taking the census. It is also greater in the more thinly settled sections of the country.

If we take the enumerators' returns, as corrected by the addition of cases obtained from physicians' registers, viz., 2,286 for Massachusetts, and 1,636 for New Jersey, the deficiencies thus corrected amount to 13.34 per cent. of the corrected returns for Massachusetts, and 20.14 per cent. for New Jersey.

If we suppose that after the addition of the 61,020 cases of deaths reported by physicians, to the returns of the enumerators, these last, excluding the States and cities above mentioned, are still deficient as much as 30 per cent, which is believed to be the maximum, the result will be an average mortality for the whole country of 18.2 per thousand of living population per annum. The actual mortality for the whole country, during the census year, was not less than 17, nor greater than 19 per thousand. This rate compares favorably with that of all other

civilized countries. The death-rate in the rural population of England, comprising ten and one-half millions of people, in the year 1880, was 18.5 per thousand. For the whole of England, for the same year, it was 20.5 per thousand. For Scotland, in 1878, it was 21.3 per thousand. In the mainland rural group of Scotland, for the same period, it was 17.3 per thousand.

The low death-rate in this country is considered to be due to the comparative absence of over-crowding, and the more general and equal distribution of the means of supporting life, including, especially, the abundant food supply of good quality for all classes of people.

The most valuable information furnished by the present census, in regard to the health of the country, is derived from those tables which show the relations of various causes of death to sex, age, and locality, since the conclusions which may be drawn from these are comparatively slightly affected by the deficiencies above referred to. The form of the Compendium does not admit the giving of these tables, which are extensive and elaborate; but a specimen of some of the deductions which may be obtained from them will be given by way of illustration.

COLOR.

In a population of 43,402,970 whites, there are recorded 640,191 deaths, giving a death-rate of 14.74 per thousand. In a population of 6,752,813 colored, there are recorded 116,702 deaths, giving a death-rate of 17.28 per thousand. Taking those States east of the Mississippi river which have the largest colored population, viz., Alabama, District of Columbia, Florida, Georgia, Kentucky, Maryland, Mississippi, North and South Carolina, Tennessee, Virginia, and Louisiana (including that part west of the river), we find that the total white population is 8,053,962, and the number of deaths recorded is 113,110, giving a death-rate of 14.04 per thousand. The colored population of the same States is 5,303,267, and the number of deaths among these reported 91,328, giving a death-rate of 17.22 per thousand. It is in this section of country that the deficiencies in the enumerators' returns of deaths are probably the greatest, and they are also probably greater among the colored than among the white population. The difference in mortality between the white and colored is especially well marked in the Southern States, and is largely due to the extensive number of deaths among infants in the colored population.

SEX.

Of the total number of deaths reported, 391,960 were of males, and 364,933 were of females, the total living population being 25,518,820 males and 24,636,963 females. For every thousand deaths of females, there were 1,074 of males. These figures give a male death-rate of 15.35 per thousand, and a female death-rate of 14.81 per thousand. It should be borne in mind, however, that the proportion of female to male deaths is somewhat greater than these figures would indicate.

AGE.

Of the 390,644 deaths of males in which the ages are recorded, 96,894 occurred under one year of age, and 163,880 under five years of age. Of 363,874 deaths of females of which the ages are recorded, 78,372 were under one year of age and 138,926 under five years of age. The proportion of deaths of males under one year of age to all deaths recorded was 248.03 per thousand; of those under five years of age, it was 419.51 per thousand. The proportion of deaths of females under one year of age to those of all ages recorded, was 215.38 per thousand; of those under five years of age it was 381.85 per thousand. The proportion to all deaths of which the ages are recorded of deaths of persons from five to fifteen years of age was 87.57 per thousand; from fifteen to sixty years of age it was 299.66 per thousand and over sixty years of age it was 172.40 per thousand.

CAUSES.

Of the total number of deaths, the causes of death were either not reported at all, or so reported as to be necessarily classed as unknown, in 23,129 cases, leaving a total of 733,764 cases of death in which the causes are distinguished. It is believed that the causes of death have been obtained much more accurately than in any preceding census, owing to the very general aid and coöperation of the physicians of the country in revising and correcting the enumerators' returns with reference to this point. To illustrate some points brought out in the tabulations which have been made, the following figures are given with regard to a few special causes of death.

Diphtheria.—The number of cases of deaths reported as due to diphtheria is, males, 18,849; females, 19,549; total, 38,398; giving a proportion of 51.33 per thousand of all deaths in which the causes are reported. The total number of deaths from diphtheria under one year of age was 2,896; under five years of age it was 20,035; between five and fifteen years of age, 16,162. In table Aa is given the number of deaths from this disease in each State Group of Counties in the United States.

In Grand Group I. (North Atlantic region), the proportion of deaths from diphtheria to the total number of deaths having recorded causes, was 51.29 per thousand, being in the cities (New Haven, Boston, Cambridge, Fall River, Lawrence, Lowell, Lynn, and Providence) 46.71 per thousand, and in the remainder of the group, including the smaller towns and rural districts 53 80 per thousand.

In Grand Group IV. (the Gulf Coast), the proportion of deaths from diphtheria was 12.16 per thousand, being in the city of New Orleans 13.74, and in the remainder of the group 12.27 per thousand.

In Grand Group VII. (being the Lake region), the proportion of deaths from diphtheria was 81.15 of all deaths reported, being in the cities (Chicago, Milwaukee, Detroit, Cleveland, Buffalo, Rochester, and Toledo) 78.15 and in the remainder of the group, 84.10 per thousand.

Enteric Fever.—The total number of deaths from enteric (typhoid) fever reported are: males, 11,852; females, 11,053; total, 22,905, being in the proportion of 31.21 per thousand of all deaths having reported causes. The total number of deaths from this disease, under one year of age, was 654; under five years, 2,707; from five to fifteen years, 3,952; from fifteen to sixty years, 13,945; over sixty years of age, 2,248.

In Grand Group I. (the north Atlantic region), the proportion of deaths from enteric fever to the total number of deaths having recorded causes, was 18.64 per thousand, being in the large cities (for list of which see above) 16.26, and in the smaller towns and rural districts, 19.95 per thousand.

In Grand Group IV. (the Gulf coast), the proportion of deaths from this disease was 22.01 per thousand, being in the city of New Orleans 7.67, and in the remaining portion of the group 30.02 per thousand.

In Grand Group VII. (being the Lake region), the proportion of deaths from this disease was 22.28 per thousand of all deaths reported, being in the large cities 17.16, and in the remainder of the group 27.31 per thousand.

It will be seen from these figures that neither diphtheria nor enteric fever are especially diseases of the large cities. They appear to be more prevalent in the small towns and rural districts which have no general water supply or systems of sewerage, but obtain their water from springs and wells, and observe the usual custom of storing excreta in cesspools or vaults.

Malarial Fever.—The total number of deaths reported as due to malarial fevers is: males, 10,276; females, 9,985; total, 20,261, giving a proportion of 27.61 per thousand of all deaths from reported causes.

The total number of deaths from these fevers, under one year of age, was 2,002; under five years, 6,182; from five to fifteen years, 3,482; from fifteen to sixty years, 7,909; sixty years and over, 26.23.

In Grand Group I. (north Atlantic region), the proportion of deaths from malarial fever to all deaths recorded, was 4.56 per thousand, being in the cities 3.02, and in the remainder of the gronp 5.40 per thousand.

In Grand Group IV., the proportion of deaths from this disease was 65.85 per thousand, being in the city of New Orleans 44.81, and in the remaining portion of the group 77.61 per thousand.

In Grand Group VII. (the Lake region), the proportion of deaths from these fevers was 9.74 per thousand, being for the large cities 8.27, and for the remainder of the group, 11.88 per thousand.

Consumption.—This is the cause of death to which the greatest number of cases are referred in the records, there being reported 40,619 males and 50,932 females as dying of this disease, giving a proportion of 124.76 per thousand of all deaths having reported causes, or a little over 12 per cent. Taking the same groups used above, we find that in Grand Group I., in the cities, consumption caused 150.55 per thousand of all cases of reported deaths, and in the remainder of the group 172.77 per thousand, giving an average of 164.89 per thousand.

In Grand Group IV., it caused, in New Orleans, 152.11 per thousand, and in the remainder of the group 97.66 per thousand, the average being 117.18 per thousand.

In Grand Group VII., it caused in the cities 97.66, and in the rural districts 130.22 per thousand, giving an average of 114.08 per thousand.

It will be seen from these figures that in the North Atlantic and Lake regions, the mortality from consumption is highest in the small towns and rural districts, while on the Gulf Coast the mortality is greatest in the city of New Orleans, in which it is higher than in the northern cities. This is probably due to the fact that New Orleans is not sewered or drained as are the northern cities, and has the soil water very near the surface.

The total number of deaths reported as due to accidents and injuries was 35,932, divided as follows: burns and scalds, 4,786; drowned, 4,320; exposure and neglect, 1,299; gunshot wounds, 2,289; homicide, 1,336; infanticide, 40; injuries by machinery, 120; railroad accidents, 2,349; suffocation, 2,339; suicide by shooting, 472; suicide by drowning, 155; suicide by poison, 340; other suicides, 1,550; sun-stroke, 557; other accidents and injuries, 13,980.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Nov. 16, 1882.

FORDYCE BARKER, M.D., LL D., PRESIDENT, IN THE CHAIR.

AFTER the reading of various reports, the scientific work of the evening was taken up. This consisted of a paper by DR. P. ALBERT MORROW, entitled

EXCISION OF CHANCRE AS A MEANS OF ABORTING SYPHILIS.

Dr. Morrow asked the question, "Is it possible by excision of the initial lesion to destroy the syphilitic virus, and prevent infection of the general system?"

The views of Bell, Hunter, and Ricord, were referred to. They advocated the early destruction of the local sore. In fact, this practice was almost universal among syphilographers until a very recent date. In 1877 Anspitz first *excised* the initial lesion. Previous to that time it had been destroyed by caustics. Since that time numerous excisions have been made, and many apparent successes reported. In Germany the current opinion is largely in favor of this practice. In France it is by no means received with the same favor, and in England the operation has been practically ignored. In this country excision does not seem to have been often practised, and the general sentiment seems to have been averse to its adoption as a means of cure. Some, however, have expressed themselves as favoring it in certain cases.

The operation consisted in lifting up with a pair of forceps the indurated tissue, together with the area of healthy tissue immediately surrounding it, and cutting off the entire mass with a single sweep of the knife. The part is dressed with a compression bandage. The loss of tissue rarely occasions much deformity. Not

infrequently secondary induration occurs, which is the indication for another operation.

It is claimed that this operation is better than the destruction of the sore by caustics or the hot iron. Also, that this simple operation prevents the occurrence of constitutional syphilis in many cases; that if it does not prevent it, the virus is attenuated and in cases of failure it has been recommended as a local adjuvant, because the local lesion is converted into a simple sore, which heals kindly in a few days.

The indication for the operation is when the sore is located where it can be removed without destroying important structures. Obviously enough, the earlier it is performed the greater the chances for success. Some recommend excision of the involved glands, as well as the local sclerosis.

Now if the initial lesion be the local expression of a constitutional condition, it manifestly follows that its removal cannot modify the effects of the disease upon the general system. In experimenting, we are embarrassed at the outset by our absolute ignorance of the nature of the virus; we are concerned with its celerity rather than the course of its progress. The question is, whether generalization of the virus occurs. At first glance it would seem that the theory of excision was the correct one; that the virus being deposited, was powerless to proceed farther until time had elapsed for repose and proliferation; that after this there was gradual implication of the vessels until the nearest lymphatic glands were reached, when it invaded the entire organism.

This conception regards the chancre as a depot of virus. To excise the chancre is to suppress the source of contagion. Opposed to this theory of excision there are many facts. In the exanthematous diseases we have, as is generally believed, local symptoms only after a period of incubation. Vaccine virus produces local trouble after a certain period, which is evidence of the complete saturation of the system.

Glanders of the horse is analogous to syphilis. Other examples might be adduced to prove that there is no possibility of interfering with the course of the poison after inoculation. The evidence furnished by clinical experience was then formulated; it was claimed that there was no distinctive signs by which a syphilitic sore could be distinguished as such before induration had occurred. Of two hundred and twenty-two cases of excision, sixty were recorded as successes, or about twenty-five per cent. By success was meant the non-appearance of secondary accidents for a period of from four months to four years. A number of objections to the acceptance of reported successful cases of excision were then given.

The author's conclusions were:

First.—That the facts of clinical experience as well as the deductions from analogy and experiment were opposed to the local nature of chancre, upon which the practice of excision was based.

Second.—The practice of excision of chancre as a means of aborting syphilis is condemned by clinical results.

Third.—The sources of error are comprehended under doubtful diagnosis, insufficient observations, and *post hoc* conclusions.

Fourth.—In cases where secondary accidents fail to appear after excision, there is no positive evidence that this immunity is due to the operation.

Fifth.—But there is no evidence that excision of chancre attenuates the syphilitic virus, or modifies the general symptoms.

Sixth.—That it cannot be recommended as a local adjuvant, since it is opposed to the practice of sound, conservative surgery.

DR. EDWARD L. KEYES was called upon by the chair to open the discussion, and in doing so he remarked that he had been very much entertained and instructed by Dr. Morrow's paper, and was glad to be able to express his entire approval of the views therein contained. He did not consider it detrimental to himself to acknowledge that there was very little more to be said upon the subject owing to the great industry that the author had displayed in collecting so large an array of evidence. Syphilis, it seemed to him, was like a beautiful woman, in that it, like her, was *semper varum et mutabile*.

The syphilis with us at the present time was not the syphilis of the fifteenth century. It is mild in consequence of civilization. Syphilis among uncivilized people is as fierce, however, to-day as ever. In support of this statement Dr. Keyes read a letter from a graduate of one of the New York colleges, who is now resident in the Sandwich Islands, in which it was stated that upon the discovery of these Islands in 1779, by Captain Cook, they teemed with population, though the exact number of inhabitants was not known till forty years ago, when it was ascertained that there were 110,000 people. To-day, there are only 40,000 inhabitants.. Before the visit of Captain Cook syphilis was unknown in these Islands, but since that time and up to the present day it has existed very generally, and in a very aggravated form, as the above statistics would seem to indicate. It was thus seen that syphilis, when implanted upon new fresh soil, was a virulent disease. Though syphilis in this city was generally very mild, still there was no safety nor certainty about it, for patients may die from it, or they may reach old age without experiencing any of its disagreeable features. This idea was supported by the fact brought forward by Dr. Morrow, namely, that though a patient may have undoubted syphilis, the case may go on in the mildest way with very little treatment. It was the animus of the great originator of the operation of excision of chancre that first directed the speaker's attention seriously to the subject. Anspitz, in putting his views before the world, thirty or more years ago, failed to recognize the work which had previously been done by others. Again, it was well known that he was a unicist. He paid very little, if any, attention to confrontation. The period of incubation was not noted with care. The only thing he depended upon was the initial sclerosis, and this was decided by the microscope. Now, microscopists did not agree as to the exact appearance of the initial lesion. It had been the speaker's experience that syphilis could be as severe as possible, and that without any hardness of the initial sore. Whether or not the microscope would reveal the evidence of specific virus before hardness had taken place, he did not know. The outcome of all experimentation is that the majority of cases have turned out to be failures. Dr. Keyes had not practised excision in a single case, but had offered to perform the operation of excision in every case where the location of the chancre would justify such a procedure. He had, however, at the same time told the patient that he could not certainly promise any benefit in the way of curing or aborting the disease, and as the patient had not requested the operation to be performed, he had had no experience with it. He thought that the evidence brought forward in Dr. Morrow's paper had settled the question of the worthlessness of the operation, and should strengthen the profession in looking upon it with more disfavor as an unnecessary procedure.

DR. E. B. BRONSON remarked that his personal experience with excision had been very meagre. In a few instances he had excised what he regarded as an initial lesion. These cases were under observation, however, only a short time. The operation was feasible in that it was easily performed, and the wound

healed kindly. So far as he knew in the cases that had come under his observation, there had been no subsequent development of the disease. It seemed to him, however, that the operation was an illogical one, for the syphilitic virus must needs have had time to have passed into the general circulation before the lapse of the time between the exposure of the patient and the appearance of the initial lesion. He had been very much interested in the paper, and heartily concurred in the views therein expressed.

Dr. George H. Fox wished to express his admiration of Dr. Morrow's paper. Although he differed from the author in some minor points, on the whole he agreed with him. He could only recall two cases in which he had performed the operation of excision. In one he circumcised the patient at the same that he excised the chancre. No symptoms of syphilis followed. In another case symptoms of syphilis followed the operation, although they were perhaps somewhat milder than in average cases of syphilis. He was inclined to think that chancre is a local lesion, and for this theoretical reason excision should result favorably. At the same time he was fully aware that clinical facts did not bear out this opinion. Practically the operation failed to accomplish what was hoped for, and hence could not be recommended as a measure of treatment. Dr. Morrow had mentioned the elements of error entering into the statistics which had been collected in favor of the operation. One of these was the impossibility of making a positive diagnosis of chancre in every case. He believed, as Dr. Keyes had remarked, that syphilis was a mild affection. He thought that the general opinion of physicians was not in accordance with this view. They were in the habit of considering the disease as of a virulent nature. He could hardly believe that syphilis as it existed three or four centuries ago was more severe than at the present time. He was inclined to think that the reports then made were very naturally made up of selected cases presenting the more striking features of the disease. We meet with severe cases of syphilis in our hospitals, but as it occurred in private practice it was certainly of a mild character in the majority of cases, for the disease ran its course as a rule without injuring the health of the patient in any appreciable degree, and many cases got well without any treatment whatever, the patients living long lives and dying of old age if not from some other disease.

Dr. F. R. Sturgis begged to supplement the objections brought forward by Dr. Morrow against accepting the statistics in favor of excision. In the cases reported adenitis was not spoken of. Now he believed that adenitis was generally recognized as being pretty sure to come on, if not at the time, at least a short time after the appearance of the chancre. A great many of Anspitz's cases were operated upon after six, eight, ten, or twelve days of incubation. One of the authors quoted in the paper reported only seven out of thirty cases of excision as successes. This seemed to him a very small proportion. In the cases reported by Frenchmen adenitis was always present, and in these cases not a single success has been recorded in support of excision. This was in striking contrast with the reports of German syphilographers, and certainly leads us to believe that there must be some error in the latter statistics. A practical point in considering the statistics of Anspitz which the author of the paper had adduced, was that he was a unicist. In this country very few experiments bearing upon excision had been made. He had only seen four cases where the operation had been performed, one of these was afterwards proven to be a chancroid. In another case, there was no subsequent induration; in all the others secondary induration followed. The absence of induration in any sore excised, must, of course, vitiate the diagnosis. Again, it was well known to those who had any familiarity with this class of cases that there were many instances of pseudo-hardness which might easily be mistaken for chancre.

Dr. Bulkley most heartily concurred with the views expressed in the paper theoretically and practically. His personal experience was limited to one case. In this instance, the chancre was thoroughly excised when the patient was first seen. Subsequently this proved to be one of the worst cases of syphilis that he had ever seen. While not believing in the prevention or abortion of syphilis by excision, there was a point which should be borne in mind in judging of the success of the cases presented in support of the operation. If one or two cases of actual syphilis are proven to have been cured by this means, the theory is in a measure proven. If it is found that by early excision of chancroid, they heal kindly and prevent subsequent destruction of tissue, the operation is of some value. It struck him that there might possibly be some value derived from the excision of all sores.

Dr. R. W. Taylor said that he agreed with most that the author of the paper had said. He would not indulge in any theory, and his remarks would only have to do with hard facts. He agreed with Dr. Keyes in the benignity of syphilis provided we had an otherwise healthy subject, docile patient, and a good doctor. This doctrine he had taught for years. He had gone into the subject of excision of chancre quite fully and without any bias. He had waited to see the result of experimentation. When he wrote the section on venereal disease in connection with his late colleague and friend, Dr. Bumstead, he had excised fifteen chancres and for good reason. Sometimes, the chancre would be found upon the end of the prepuce, and would give rise to phimosis. Two procedures, under these circumstances, were open to the physician. One was to cut away the chancre or to excise it; the other to give mercury internally. The first method removed the sore with a single stroke, the other necessitated the commencement of treatment earlier than was desirable. Under circumstances like these, he considered it conservative surgery to excise the chancre. As early as 1869 he had excised his first chancre, and as above stated, by the time of the publication of his book had operated upon fifteen patients. But the disease came on subsequently. In three or four cases there was some enlargement of the glands. In two cases he was astonished at the length of the period of secondary incubation; namely, seventy-two days in one and seventy-nine or eighty days in the other. This observation was the means of keeping up his interest in the operation. He remembered an old time friend of his, in whom the first period of incubation was sixty days, of which he was satisfied. From that time, after having the chancre excised, it was seventy-two days before the disease made its appearance. The symptoms in this case were mild. The course of the disease, however, in the patient's wife, to whom he had communicated the disease, and who was of a tuberculous disposition, was severe and resulted in her death.

Dr. Taylor recited the history of a case which he thought settled the question. The patient came to him showing a little excoriated papule not larger than the heads of four pins. It was red and slightly elevated. The patient was of a nervous temperament and very anxious about the sore. He stated that twenty days previous he had had connection and that he could submit the woman for examination. On the evening of the same day Dr. Taylor examined this woman, and found at the fourchette a small excoriation and a declining roseola on her body. Dr. Taylor stated the case to his patient, saying that the sore which he had

upon his penis was probably an initial lesion of syphilis which could be determined positively by letting it go on undisturbed. But the patient did not wish to let it go on, and, in accordance with his request, the sore was excised. Previous to the performance of the operation the penis was washed in a watery solution of carbolic acid. The sore was then touched with the pure acid so as to destroy its virus and prevent exudation into adjacent healthy tissues. It was then dusted with calomel, transfixed, and cut away together with an abundance of surrounding healthy tissue. The wound was allowed to heal by granulation, and in the course of ten days had closed nicely. No enlargement of the inguinal glands followed. Dr. Taylor wished, however, to state that he had seen cases of syphilis where the initial lesion was not excised, in which inguinal ganglia had escaped enlargement until a later period in the disease. This man had no enlargement of the inguinal gland, but at the end of forty five days he presented himself at the office, having taken a Russian bath the night previous, with a roseola coming out. As a prophylactic, he considered excision a failure.

DR. OTIS said that it was not his object in rising to speak to criticise the paper nor the experience of those physicians who had thus far spoken, but he wished to give his own experience and the views he entertained upon this subject. It seemed to him that in order to form an opinion of the desirability of excision of the initial lesion, it was necessary to inquire what the initial lesion is. He thought there was sufficient authority to enable us to say that the beginning of syphilis was an infected cell which could not be distinguished in any way from the white-blood corpuscles. We had a right to assume this from the fact that the first condition which we recognize at the point of lesion is a proliferation of cells. That these cells are not the result of an inflammatory aggregation of cells, but that they are the result of proliferation. Sufficient evidence existed to show that syphilis may go on through its entire course without any open lesion of any kind, the only observable condition being a small primary nodule. There must have been, however, an opening for the introduction of the syphilitic virus, but that this healed kindly was just as certain. In 1867, Biesiadecki made a careful microscopical examination of twenty specimens of Hunterian chancre, and found that there was in every case a proliferation of cells. He found the cells aggregated at the point of lesion to such an extent as to interfere with their own nutrition and secondarily the nutrition of the part. The lumen of vessels became packed with cells as well as the lymph spaces, and this packing of cells resulted in the interference with the processes of nutrition to the extent of causing a superficial exfoliation and breaking down of tissue, thus making an open sore. It was further found in examining the lymphatic vessels proceeding from this point, that those vessels were packed with cells and successively so throughout the line of the lymphatic vessels. There was no such general invasion of the patient with infection, as might have been supposed. Twenty, thirty, forty days would elapse from the time of exposure to the appearance of the initial lesion. This process of cell proliferation had gone on until it reached the lymphatic glands and through a period of at least six weeks in the majority of cases before any general evidence of the disease had manifested itself. This first period had been termed the period of incubation. All authorities had found the same condition, namely, the accumulation of cells first at a certain point and afterwards, at the end of a period varying from four to five and six weeks, there has been a general manifestation of syphilis in the shape of roseola eruption. Now, during all this time there has been nothing external or internal to show that the disease was present, and this fact is strong evidence of the local nature of the disease. Now, when we talk about excision of chancre with a view of arresting the disease, we know with what we have to deal. We have a proliferation of cells at a particular point. It depends upon the rapidity with which these contagion-bearing cells are enabled to get away from this point, whether we can prevent the disease from going into the general system. If we can take it early enough, the speaker believed that it was possible to prevent the occurrence of subsequent syphilis by excision. If the glands were involved, we could hardly hope to profit largely by the operation except by excision of the glands. As to affording relief from constitutional infection, this matter must always be a question of circumstances. It must vary in various instances. It might move with great rapidity from the surface through the lymph spaces into the lymph vessels—that is, from the surface towards the glands.

As to the practical results in at least fifteen, perhaps twenty, cases of excision which had been performed by the speaker, he would say that very great benefit has accrued from the operation as a matter of personal convenience in a number of cases. In illustration of this statement, the following case was cited. A patient came into the speaker's office, a number of years ago, with a very large initial lesion of syphilis upon his penis. He said he had been under treatment between two and three months, and that the sore was still increasing. He had just received a telegram to the effect that his wife was about to return home from Europe, and would probably reach him in the course of ten or twelve days. As a means of speedy relief, excision was advised and readily consented to. On the third day after the operation the wound had entirely healed by first intention, and when his wife reached home there was only a small line to indicate the seat of the former sore, which was a source of much satisfaction to the patient. As to the operation destroying much tissue, he wished to state in the first place that such was not the case, for the tissue which was removed was superfluous tissue. Hence the removal of the disease did not cause much, if any, deformity. In a number of cases operated upon he had found some difficulty some months afterwards in determining the exact seat of the former lesion, even in cases where the part excised was as large as the end of his thumb. While he would not claim it very strenuously, it had seemed to him that in the cases he had operated upon, the subsequent manifestations of the disease were milder than usual. This was the impression made upon his mind from his personal experience. He had not observed any tertiary manifestations of the disease in the patients operated upon. While appreciating the possible benefits to be derived from excision of the initial lesion he would never expect to have this take the place of legitimate treatment.

DR. OTIS said that some two years ago he had an opportunity to practise excision of an erroded papule on a worthy member of our profession.. Some months afterwards he came into the office stating that at the time of the excision of the initial lesion he was of the opinion he must have syphilis. He stated that he knew he had syphilis, for he had just seen the young lady with whom he had connection, and she now had a papuli syphili. He was perfectly confident that he did not now have syphilis, and he wanted to claim for the operation of excision the curability of syphilis. He stated that he was now entirely free from syphilis, but that the woman with whom he had had connection before the excision of the sore had syphilis. Dr. Otis, however, was not so easily satisfied and submitted the patient to a thorough examination, the result of which was the recognition of the fact that he had inguinal enlargement on both sides; inspection of the throat

revealed a condition of comparative health, though there was some redness. Upon drawing aside the tongue with the spatula, a mucous patch was disclosed. The patient went under a course of constitutional treatment, which had just now been ended after a period of nearly two years. This case would have been very readily taken as an example of proof of the benefit of excision, had not much care been taken.

As to the non-malignancy of syphilis he was not at all convinced; on the contrary, he thought that in the wards of our hospitals could be found many cases illustrating the great virulence of the disease.

In private practice the mildness of the cases was in consequence of the judicious treatment which they received at the hands of physicians. He thought that the general intelligence of the profession was very excellent regarding the treatment of syphilis.

The discussion was closed by a few remarks by Dr. Morrow.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, October 9, 1882.

THE PRESIDENT, DR. JAMES TYSON, IN THE CHAIR.

MYXOMATOUS TUMOR OF THE POSTERIOR CERVICAL REGION,

presented by DR. NANCREDE, for Dr. W. G. MacConnell.

The tumor was removed by Dr. J. H. Brinton, at the Jefferson College Hospital Clinic, some ten days since. The patient was a little boy aged four years, whose parents had first noticed the growth about two years ago. Latterly, it has grown with considerable rapidity. It was of firm consistence, lobulated, and movable beneath the skin, giving the impression that it was a fibrous tumor. After removal, in addition to the above-mentioned characteristics, it was found surrounded by a capsule, and on section looked somewhat suggestive of myxoma, still it was thought by some to be merely a fatty tumor containing more fibrous tissue than usual.

Microscopic Examination (by Dr. MacConnell).—Upon examining a frozen section stained with iodine, meshes of capillaries are seen displayed, in the walls of which the endothelial cells composing the vessels can be distinctly seen. The aforesaid meshes contain the mucoid structure traversed by large pale fusiform cells, the processes of which anastomose with each other. In addition, many leucocytes are seen, and interspersing the growth in every direction numerous yellow elastic fibres are readily distinguished.

When presenting this specimen Dr. Nancrede commented on the rarity of such growths.

DR. S. W. GROSS said he had himself presented several gelatinous polypi of the nose, a number of years ago, which were most characteristic examples of myxomatous tissue. He could also recall a specimen of subcutaneous myxoma of the forearm, as well as the hæmatoid myxoma of the breast referred to by Dr. Nancrede. He was disposed to consider it the rarest of all neoplasms of the breast; indeed, he had never personally met with one, and when preparing his work on tumors of the breast, he had written to numerous surgeons throughout the country, who all replied that they had never met with one affecting the breast.

DR. FORMAD remarked that he had exhibited a myxomatous fibroma of the labium some years since, and said that the peculiar milky appearance assumed by the fluid, when such growths were thrown into alcohol, was a good diagnostic point.

DR. SHAKESPEARE said that his personal experience as to the rarity coincided with that of Dr. Gross. This specimen is one of the rarest forms, as most of the fibrillæ consist of yellow elastic tissue. The rarity of myxomatous tumors seems to him to have much bearing on the views of Cohnheim and others as to the etiology of tumors. The observers insist that all tumors spring from the remains of fœtal tissues, not made use of in tissue construction, which remain dormant in their embryonal condition until subjected to some irritation, when they develop into the various neoplasms. New tissue, practically identical with that found in myxomata, pervades the fœtus. How then is it that portions of this do not remain to give rise to myxomata? On the contrary, myxomata are among the rarest of the neoplasms.

SPECIMENS FROM A MAN WHO DIED WITH BRAIN, LUNG, HEART, LIVER, SPLEEN, KIDNEY, AND BLADDER LESIONS,

were presented by DR. J. F. T. ESKRIDGE.

The specimens showing the above lesions were removed from the body of a man, aged 68 years. The patient had become deaf in the right ear thirty years before, while suffering from some brain disturbance. Attacks of jaundice, with gradually increasing permanent discoloration of the skin, had extended over a period of ten years. Since the early part of the year 1877 he had complained of incontinence of urine, an oppressed feeling over the hepatic region, dropsy in the feet and face, and a gradual loss of flesh and strength. The two years preceding his death he had been unable to work, but was only confined to bed five days. During the latter period his symptoms were, in the order in which they were developed, great prostration, scanty secretion of urine, blindness for twenty-four hours preceding repeated convulsions, loss of speech, and almost total inability to swallow, although consciousness was preserved until coma ushered in the death scene. His temperature (axillary) did not rise above 100.5°. The surface head temperature nearly equalled that of the axilla. No paralysis of the muscles of the face or extremities preceded death. The liver during life did not appear to be enlarged or altered in its outline.

The *post-mortem examination* revealed in the brain engorgement of the veins, with some effusion, slight pia-mater inflammation in the neighborhood of the fissure of Rolando, apparent degenerative changes in the left island of Reil and anterior portion of the left temporo-sphenoidal lobe; in the pleura and lungs, old and numerous pleuritic adhesions, lobular and vesicular emphysema of the lungs, congestion of both lower lobes, and a nodule (probably cancerous) of the left apex; in the heart, fatty degeneration, dilated right ventricle, and incompetent mitral valves from ossific change; in the liver, multiple cancer without an increase in size or a nodular condition of the organ; in the spleen, marked increase of fibrous tissue and atrophy of the gland to one-half or less its normal size; in the kidneys and ureters, the last stages of pyo-nephrosis, the glandular tissue being nearly all destroyed, the pelves were as large as a good-sized orange, and the ureters dilated so as to admit a man's thumb; in the bladder, great hypertrophy of the mucous membrane and decrease of the capacity of the viscus.

PRIMARY CARCINOMA OF PANCREAS AND LIVER.

Presented by DR. E. T. BRUEN.—The interesting features pertaining to this case are the age of the patient—24 years, and the rapidity of the abnormal processes. These rendered the diagnosis of malignant diseases doubtful until the appearance of nodular tumors in the liver. The family history was free from hereditary disease. The commencement of the disease dated from September 1, 1881; death occurred on the 15th of January, 1882. At first the symptoms related solely to the digestive tract, such as dull and

heavy sensation after eating with acid eructation and occasional vomiting. Subsequently sharp, cramp-like pains in the abdomen were a prominent symptom. After the lapse of a week there commenced general itching, and two week later the skin became yellow. This yellowness and itching never disappeared during the history of the case. At the autopsy the gall-duct was obstructed by the enlarged head of the pancreas, so that extreme dilatation of the gall-bladder had ensued. This was probably the cause of the jaundice and not the liver disease itself. The bowels were regular and the appetite good when first seen. The case then presented evidences of partial obstruction of the gall-duct with digestive disorder, but without the symptoms characteristic of malignant disease of the stomach or bowels. By the middle of December, 1881, the liver dulness extended from the fourth interspace to three inches below the ribs in the upper nipple line; from the ensiform cartilage the line of dulness extended to within one inch of the umbilicus. The hepatic region was tender on pressure, especially over the epigastrium. The patient complained about this time of dull pain over the liver, with griping pain in the abdomen. The pulse was 76 per minute. He had lost four pounds since admission and looked thin. About this time a small inequality was noticed in the surface of the liver three inches above and a little to the inner side of the umbilicus. Tho spleen was enlarged. By January 7th, the bossillation of the liver became distinct and the enlarged gall bladder, rendered irregular by gall-stones, presented a slowly increasing, elastic, tender tumor, situated to the right of the epigastrium and umbilicus. By Januray 12th, the pulse became rapid—130 per minute; the patient rapidly failed and death occurred January 15th.

Autopsy.—The pancreas was enlarged to double its size, the growth chiefly occupying its head and compressing the common bile-duct. Microscopic examination showed it to be scirrhous carcinoma. The liver was thickly studded with nodules of medullary carcinoma, explaining the *ante-mortem* bossillated feel of the organ. The gall-bladder was distended to twice its normal size and contained a number of gall-stones.

Remarks.—The duodenal end of the organ, as is usual, was the seat of the disease. In a paper on 39 cases of primary carcinoma of the pancreas in St. Bartholomew's Hospital Report for 1881, jaundice is stated to be always present, while in 24 cases of secondary carcinoma this symptom was noted in but seven cases. This is presumably from the secondary growth occurring in some other portion of the organ than its head. Murchison says that the characteristic symptoms of carcinoma of the pancreas are, pain in the pancreatic region, sensible tumors, and persistent jaundice. To these Dr. Bruen would add, intestinal dyspepsia, which differs in some essential features from the dyspepsia of organic disease of the stomach.

DR. MUSSER remarked that he could vouch for there being a distinct tumor of the pancreas, as he was present at the autopsy. The case had been under his observation in the dispensary one month prior to admission to the hospital. On account of the age he was puzzled as to an exact diagnosis, although confident that the cause of the jaundice was obstruction. He noted among other symptoms the intense itching of the skin, a point of importance, Sims says, in the diagnosis of obstructive jaundice from that due to suppression. Of five cases of tumor of the pancreas he had lately seen, all were accompanied by jaundice.

DR. BRUEN called attention to the uncertainty of bossillation as a symptom of malignant disease of the liver. He had presented to this Society only two weeks since a liver exemplifying this condition in a marked degree, where nothing beyond cirrhosis in the stage of enlargement existed. The occurrence of carcinoma of the liver at so early an age is unusual, although Dr. Pepper had shown a specimen of the disease to this Society some years ago, occurring in an infant.

The PRESIDENT said that there were two points in this case of great interest to him: firstly, jaundice in carcinoma of the pancreas, while it is a frequent symptom, it is by no means an invariable symptom. Seven years ago he presented to this Society the specimens from a case of primary pancreatic carcinoma, where no jaundice had been present, and six months ago he presented to the Society a specimen of enlargement of the head of the pancreas from a patient who also presented no symptoms of jaundice. Secondly, as to the diagnosis from cancer of the stomach, he had noted in his experience, as was mentioned in the history of Dr. Bruen's case, the absence of gastric symptoms. This negative symptom is of importance, since the tumor is often detected in precisely the same spot in both these diseases. The absence of gastric symptoms with intestinal indigestion, irrespective of fatty diarrhœa, he considered the most reliable diagnostic points between carcinoma of the pancreas and stomach.

SPINDLE-CELLED SARCOMA OF THE SMALL INTESTINE,

presented by DR. W. A. EDWARDS.

On September 23, 1882, I was asked to assist Dr. W. F. Atlee in the removal of an abdominal tumor. The patient, æt. 48 years, whose menstruation had ceased at 31 years, first noticed the swelling in April last. On the day of operation she measured thirty-eight inches around the abdomen. The usual incision was made, and the tumor reached, when its surface was seen to be of a dark purple hue, with a network layer of veins, ramifying in every part of its serous covering. A trocar and canula were introduced, but nothing but blood followed the withdrawal of the trocar. The sac was then torn open, and its contents of a soft brain-like consistence were emptied out. The growth was now turned out of the abdominal cavity. There was no distinct pedicle, but an attachment to the intestine of about the size of a half dollar was seen. Dr. Atlee says, "when I emptied the sac of its soft contents I examined carefully, with *extreme care*, the part fastened to the intestine, and my fingers passed into the intestinal tube." A silk cord was tied around the attached portion, and the remainder of the growth removed. The omentum was attached to the growth for a space of two inches; this was ligated and cut away, and the abdominal wound was closed, etc. Death occurred on September 25, at 4 A.M.

This growth sprang primarily from the submucous tissue of the small intestine, and grew with great rapidity as the patient was only aware of its presence last April, and by September she measured, as above stated, thirty-eight inches. *Microscopical* examination of preparations, taken from several portions of the growth, clearly show it to be a spindle-celled sarcoma, and a most typical one at that. The small intestine is an unusual site for this neoplasm. As far as I am able to ascertain there is no recorded instance of its occurrence in this situation. My friend, Dr. Formad, to whom I have shown the growth, concurs with me in this statement. On the day of operation I noted, as well as I could, the absence of all secondary deposits. The surrounding intestines and peritoneum were apparently normal, not even unduly hyperæmic.

No post-mortem was permitted.

CHRONIC PARENCHYMATOUS NEPHRITIS COMPLICATING PHTHISIS PULMONALIS,

presented by DR. JAS. TYSON.

My object is showing these kidneys is to illustrate the morbid anatomy of the renal complications which

so frequently attends the later stages of phthisis pulmonalis. It is very well understood that when œdema of the feet and legs presents itself in cases of consumption the end is not far distant; but the renal complication which is at the bottom of such œdema is often overlooked. It is of course not impossible that there should be œdema in the last stages of phthisis, from simple alteration in the composition of the blood—a watery state of it—but in the majority of instances it means that the kidneys have become involved. As to the form of disease affecting the kidneys, it is acknowledged that it may be either lardaceous disease or chronic parenchymatous nephritis, but I think the impression prevails, it was at least my own until recently, that the amyloid kidney is the most frequent complication. I believe, however, that the chronic parenchymatous nephritis is more common, and it becomes a matter of interest, if not of importance, to be able to diagnose between these two conditions. It is well known that the microscopic and clinical characters of the urine in these two forms of kidney disease are often identical, so that no assistance is afforded by a study of the urine. The history of the case, of course, leads to neither particular form, but suggests both. One criterion only can I recall to aid us, and that is the presence of enlarged liver. So commonly associated is the enlarged amyloid liver with amyloid kidney, that the absence of it almost necessarily precludes the presence of amyloid kidney. At least I am sure we would err less frequently if we were to consider all cases of renal disease attending consumption unattended by enlarged liver to be parenchymatous nephritis rather than lardaceous disease. It is true we often have enlarged fatty liver in consumption, but the degree of enlargement never reaches that of amyloid liver, and hereafter I shall be inclined to consider all cases of renal disease complicating consumption to be parenchymatous nephritis unless they are associated with enlarged liver, when I shall conclude that they are instances of amyloid disease.

Dr. Bruen considered that the passage of large quantities of urine, and the history of specific disease or of prolonged suppuration preceding the kidney trouble would warrant a diagnosis of amyloid renal disease.

DR. MUSSER would ask whether the heart was hypertrophied, and what was Dr. Tyson's experience regarding hypertrophy of that organ in cases of amyloid disease and of chronic tubal inflammation of the kidneys. If not too late, he would like to call attention to the absence of cardiac hypertrophy with an infinite degree of obstruction in the renal circulation in the case Dr. Eskridge had presented. This is in direct opposition to the view held by some that the hypertrophy of the heart is a sequence of the renal obstruction in chronic interstitial nephritis.

DR. TYSON replied, that in this particular instance he did not see the heart and could not tell whether it was hypertrophied or not. The same law holds good for amyloid kidney, as for chronic nephritis; if the case last long enough, hypertrophy is sure to be found sooner or later.

ECCHYMOSES OF THE MUCOUS MEMBRANE OF THE STOMACH,

presented by DR. J. M. BARTON.

The history of the case was that of chronic lung trouble. The stomach upon being opened presented an irregularly shaped extravasation of blood about two-thirds of an inch in diameter. The mucous membrane covering the effusion was healthy, as it was in the rest of its extent.

DR. TYSON remarked that these effusions are not uncommon, but he has never seen them except in their pin-point form.

DR. ROBERTS asked if there had been violent vomiting recently.

DR. BARTON replied that nothing of this sort had been observed for some months prior to death.

CORRESPONDENCE.

SEWER-TRAPS.

To the Editor of THE MEDICAL NEWS.

SIR: In reply to your late strictures upon my paper entitled, "Why Sewer-traps are Unreliable," etc., I hope you will permit me to explain briefly: 1. That when speaking of traps emptying by evaporation, siphonage, etc., I was not so stupid as to deny such occurrences, but only sufficiently so to dispute their importance, if, as I believe, new depots for the reproduction of disease germs frequently form inside these boasted safeguards. 2. That, although reporting observations on three traps only, I too often quote to students the aphorism that "no one fact, and, indeed, no ten facts, prove anything in medicine," to fall into the error of limited experiment you impute to me. Before my paper was published, I learned from practical plumbers that a slimy lining, such as I described, is a common and troublesome intruder into ball, S, and D traps, and the usual denizen of sewers. 3. Your statement that the vegetable growth I examined was entirely different from that which characterizes the development of those microzymes which are capable of causing disease, because it consisted of creeping threads, "whereas the germs which we know anything about are minute particles or single cells," could only have proceeded from a want of personal acquaintance with the subject, since it is notorious (among microscopists) that the diseases of *Favus* and *Herpes circinatus* are caused by spores and mycelia (creeping threads) of the achorion and microsporon *intruding* among the epithelial cells of the hair and skin. Finally, it seems to me that your assertion, "The gases of sewers do not cause any specific disease," is *very bad for the facts* I have quoted from Thursfield, Keating, Chamberlin, and Wilson, and which are recorded by a host of medical and sanitary authorities.

Very respectfully yours,

JOS. G. RICHARDSON.

3238 CHESTNUT ST., PHILADELPHIA, Nov. 16, 1882.

[The fact that Dr. Richardson found a fungous growth in a ball trap proves nothing with regard to an S trap, which is the trap commonly used and recommended. The production of *specific* diseases by sewers is not due to the gases but to particulate germs. The essential point is, has Dr. Richardson presented any evidence that a fungoid growth has ever been known to creep from a soil-pipe through an S trap to the house side? It is our opinion that he has not and that there is no foundation for his sweeping generalization that the theories held by most, if not all, sanitarians and sanitary engineers may be relinquished.—ED.]

NEWS ITEMS.

BROOKLYN.

(*From Our Special Correspondent.*)

THE MEDICAL SOCIETY OF THE COUNTY OF KING'S AND THE NEW YORK CODE.—At the stated monthly meeting of the King's County Medical Society held last Tuesday evening, the special order of business was the consideration of Dr. Squibb's resolutions offered at the preceding meeting (see THE MEDICAL NEWS for November 4, page 530). The meeting was very largely

attended, and the resolutions of Dr. Squibb were adopted on a vote taken by ballot. The effect of the vote is to instruct the County Society's delegates to the State Society to vote in the interest of the old Code.

PROGRESS OF THE YELLOW FEVER.—Official yellow fever reports have been received at the office of the Surgeon-General U. S. Marine Hospital Service to include the 10th of November, showing that only six cases and one death have occurred at *Brownsville* since the last weekly report. This makes a total of 2006 cases and 15 deaths since the disease appeared at that place. One case appeared at Point Isabel, Texas, on the 4th inst. The weather is reported hot and calm.

The *Cordon Sanitaire* thirty miles above Brownsville, known as the "Arroyo Cordon," was removed on the 10th inst.; but the river guards in Hidalgo and Starr Counties bordering the Rio Grande are continued, owing to the prevalence of the disease in Mexican towns confronting those counties. Dispatches state that people returning to Mier and Camargo, in Mexico, are falling victims to the disease, 11 deaths at the former and 7 deaths at the latter place having occurred on the 2d and 3d of November.

The yellow fever epidemic in *Pensacola, Florida*, is happily at an end, although no official announcement to that effect has been made. During the past week ending November 20th, two telegraphic reports have been received at the office of the National Board of Health, one on the 14th stating that no new cases had been reported during the previous twenty-four hours, and the second on the 16th reporting 5 sporadic cases, but no deaths. Since then many suppose that there have been no new cases to report, else force of habit would have led the Secretary of the Pensacola Board to his telegraph book. The report on the 16th stated that there had been a frost during the three preceding nights.

DIPHTHERIA IN PHILADELPHIA.—The continued prevalence of diphtheria in Philadelphia has been the cause of considerable comment. Since 1876 the disease has not been so fatal as it is at the present time. In the former year there were 708 deaths from this disease; in the present year the records show that there have been 730 deaths up to November 18th, which number is already in excess of that of any previous year.

The mortality for the preceding eleven years was as follows:

1871, . .	145 deaths.	1877, . .	458 deaths.
1872, . .	150 "	1878, . .	464 "
1873, . .	110 "	1879, . .	321 "
1874, . .	179 "	1880, . .	323 "
1875, . .	652 "	1881, . .	457 "
1876, . .	708 "	1882(Nov.18),	730 "

For many years previous to 1875 the mortality from diphtheria was comparatively light, it never having exceeded 200 deaths in any one year. Going back to 1861, we find the deaths amounted to 502, which indicates a mortality relatively about as great as that of the present year. In 1875 there was a marked increase in the deaths from this cause, the number having been only twice exceeded in the past decade, namely, in 1876 and in 1882. Since 1876 there has been a gradual falling off in the annual number of deaths until 1881, when an increase again occurred, which has been particularly marked the present year.

The deaths by quarterly periods in 1882 have been as follows: 1st quarter, 174; 2d quarter, 163; 3d quarter, 215; from October 1st to November 18th, 178.

The disease has been more especially prevalent since the latter part of August. Since the week ending August 26th, the average weekly number of deaths has been about 23. In September there were 108 deaths; in October, 84; and in the first three weeks of November, 94. The total mortality for November will in all probability exceed that of any previous month.

It has been stated that the frequent and prolonged exposure of the people during the Bi-Centennial Celebration, held during the week ending October 21st, by acting as a predisposing cause, accounts for the present increase of the disease. While this may be to some extent true, it fails to explain the much greater mortality which occurred in the month of September.

The disease does not seem to depend on localized causes, for, while it is more prevalent in Frankford, and in wards in the northeastern part of the city, deaths are reported from many widely separated localities. It is almost entirely confined to children, the period between two and five years furnishing the greatest mortality. As a rule, this disease is most prominent in the first and last months of the year, and its increased prevalence at the present time, therefore, is no exception. Compared with other large cities, the mortality in Philadelphia is not excessive, New York having reported as many as forty-four deaths in one week during the present year.

TYPHOID FEVER IN PROVIDENCE, R. I.—In a communication to the Board of Aldermen, on November 16, the Superintendent of Health, Dr. Edwin M. Snow, makes a statement of the facts as known to him concerning the present outbreak of typhoid fever in the city, with the view of correcting the false and exaggerated rumors which are prevalent, and causing increasing alarm and uneasiness among the people.

During October the mortality returns did not show any unusual prevalence of the fever, as only eight deaths occurred from this cause during the month, or two less than during the preceding month. But four or five days before the end of October a sudden outbreak of the disease was observed in all parts of the city, as well as in neighboring towns, as East Providence and Seekonk, Mass., and the disease is still progressing. Dr. Snow has entire confidence in the purity of the Patuxet water, which forms the main supply of the city, and points in support of this opinion to the fact that the fever is more prevalent in proportion to population in East Providence and Seekonk than in Providence.

During the week ending November 4, 51 cases were reported, in the following week 163 cases, and during the four days to noon of November 16, 68 cases, making a total of 282 cases.

Dr. Snow thinks it probable that all the cases have not been reported, but is inclined to believe that the whole number does not exceed 400.

Of the whole number of cases, the comparative severity was reported as follows:

Mild, . . .	70 cases, or 24.8 per cent.
Average, . .	126 cases, or 44.7 per cent.
Severe, . .	36 cases, or 30.5 per cent.

None were reported malignant.

SCARLET FEVER IN COLUMBUS, O.—Dr. Doren, the Superintendent of the Institution for the Feeble-Minded in Columbus, makes the following statement to a *New York Herald* reporter about the spread of scarlet fever in the Institution: "Since the 10th inst., we have had fifty-eight cases. Three have died. One was very low this morning. The general character of the disease is mild, but it may extend to all the inmates who are liable to take it, as the Institution is crowded in consequence of the destruction of one of our buildings by fire on November 18, 1881. There is a new building nearing completion."

The Typhoid Epidemic at Paris.—The rapid extension of the epidemic of typhoid fever in Paris is exciting considerable consternation, and well may do so. The mortality has increased fivefold in the course of three weeks; from 57 in one week to 134 in the next, and 250 in the third. The number of admissions into hospital has exhibited a corresponding increase, being 213 in the first, 536 in the second, 1001 in the third, while on October 19th, the various hospitals contained no less than 2136 cases. Since then a slight fall in the number of fresh cases has occurred, which, it is hoped, indicates the commencing decline in the epidemic. The epidemic is most severe in the northern quarters of Paris, the mortality at La Villette being five times as high as at Montrouge. Of 250 deaths in the last week, 42 were between the ages of five and fifteen, and 167 were between fifteen and twenty-five. It is conjectured that the extension of the disease may be connected with the return to Paris of many families, especially students and others, who have, during a holiday spent in the country, lost some of their acclimatization; but, on the other hand, it must be remembered that the present season of the year is that in which typhoid most frequently assumes an epidemic form. The circumstances of the outbreak, however, unquestionably deserve the most careful study, since its extent threatens to render it one of terrible proportions. It is remarkable as occurring in a season of much and persistent rain, in which the chance of the contamination of drinking-water is usually regarded as small.—*Lancet*, November 4, 1882.

Quarantine Quarrels.—A difference of opinion as to the propriety of discontinuing quarantine regulations on November 1st, has given rise to a warm correspondence between the health authorities of Louisiana and Texas. The State Board of Health of Louisiana having ordered quarantine regulations to be suspended on that date, the health officer of Texas announced in a letter to Dr. Joseph Jones, President of the Louisiana Board, that the presence of yellow fever in Cuba, Pensacola, and along the western border of the State, had caused the governor to extend the quarantine until cold weather, and that as it would be useless for Texas to maintain a quarantine against infected places if New Orleans was open to them, the regulations would be enforced against that city if its quarantine was raised on November 1st, as suggested.

Mr. A. Pearce Gould has just been elected Assistant Surgeon to Middlesex Hospital, London. Mr. Gould is favorably known in this country as the author of numerous contributions to surgical literature, the latest and most noteworthy of which is the elaborate paper read before the late International Medical Congress, on the rapid method of cure of external aneurism by means of the elastic bandage, with a table of 72 cases.

University of Aberdeen.—Dr. Alex. Ogston has been appointed to the Chair of Surgery in Aberdeen University.

Berlin Gynecological Clinic.—The new Berlin Gynecological Clinic was opened on October 18th. The occasion was celebrated by the presentation of an album containing the photographs of all the earlier directors and assistants.

The Illness of Sir Thomas Watson.—The *British Medical Journal* gives the following account, by Mr. John Walters, physician in attendance, of the illness of Sir Thomas Watson, which will be read with a sad interest by his many admirers on this side of the Atlantic:

Sir T. Watson, now in his ninety-first year, had returned a few weeks ago from the seaside, and was staying with his son at Reigate Lodge, previously to returning to London for the winter, and was in the enjoyment of his usual good health. On Sunday afternoon (October 22d), after rising from his chair, he found he was unable to stand, and, inclining to the left, would have fallen if he had not received support from those at hand; subsequently, in trying to write a letter, he could not remember how to spell the simplest words.

On visiting him two hours after, I found him perfectly rational and collected. He said he could not explain his symptoms; he felt perfectly well, but could not stand without help; when he tried to do so, he fell over to the left side. The pupils were somewhat contracted, equal, and answered to the stimulus of light. Pulse 78, regular; arteries somewhat rigid and tortuous; heart-sounds very feeble, with a metallic ring over the aortic valves; extremities rather cold. There was no apparent paralysis, but the face was slightly flattened on the left side, and the tongue inclined somewhat to the left. He was able to walk up-stairs to bed with assistance. The urine was found afterwards to be alkaline, but contained no albumen. The temperature was subnormal. He passed a fair night. On the 25th he was seen by Dr. G. Johnson with me. His condition was much the same as when first seen, and he was able to take a fair amount of nourishment and some stimulant. On the 26th, after slight exertion, an alarming attack of dyspnœa came on, with coldness and lividity of the extremities. This passed off after the administration of some stimulant, and he walked to his bed-room with assistance.

On the 27th he took but little nourishment, and was much exhausted; he became drowsy towards evening, and his tongue dry and parched. As his condition seemed alarming, Dr. Greenhow was asked to see him with me. The next morning we found his condition much improved; the temperature normal: tongue moist, but coated with a white fur; the pulse 84, and regular. He had taken light nourishment, and slept for some hours; he was perfectly sensible, and had no further paralytic symptoms. Since this his condition has varied but little; and, on being visited by Dr. Johnson again on the 28th, he found him in just the same state as he was on the 27th. During the last few days, the pulse has gone down to about 60, regular, of fair quality; he has no obvious paralysis; the face and tongue remain as when first seized, except that the flattening of the left side of the face is more marked. The urine has become acid, and now contains a trace of albumen. The breathing is at times irregular when asleep, approaching the condition known as "Cheyne-Stokes'" respiration; the bowels have acted several times without assistance; and the urine is voided naturally. He only takes the lightest kind of nourishment, dozes a good deal, and usually sleeps several hours during the night. He has not been able to leave his bed since the attack on October 26th; he is easily roused if dozing, and his mind remains quite clear.

The opinion we have formed is that there is thrombosis of some of the smaller cerebral arteries on the right side (probably supplying the region of the parieto-occipital fissure). The prognosis is naturally grave.

Health in Michigan.—Reports to the State Board of Health, for the week ending Nov. 11, 1882, indicate that puerperal fever, bronchitis, tonsillitis, cholera morbus, membranous croup, dysentery, and rheumatism, increased, and that erysipelas, typhoid fever, and typho-malarial fever, have decreased in area of prevalence.

Reports from sanitary inspectors, during the week

ending Nov. 11, mention three cases of measles found among immigrants arriving at Detroit.

Including reports by regular observers, and by others, diphtheria was reported present during the week ending Nov. 11, and since, at 25 places, scarlet fever at 19 places, measles at 4 places. Smallpox was reported at Grand Rapids Nov. 11.

OBITUARY RECORD.—Died, on November 20, in the forty-sixth year of his age, HENRY DRAPER, M.D., late Professor of Chemistry in the University of the City of New York.

Professor Henry Draper was a son of the late Dr. John William Draper, the eminent chemist and philosophical writer. He was born in Prince Edward County, Va., March 7, 1837. He graduated in the medical department of the University of New York in 1858, and in 1860 became Professor of Physiology and Analytical Chemistry there. Dr. Draper remained at his post in the Medical School until 1873, when he resigned the office, retaining, however, active relations with the Academic Department until last September. Together with the study of physiology he taught analytical chemistry for several years, taking the students after they had been two years in his father's class, where they had been carefully instructed in the elements of the science. After the death of his father, he was elected to fill his chair.

He published a "Text-Book of Chemistry" in 1864, and has been a frequent contributor to scientific periodicals, principally on astronomical, electrical, and photographic subjects. He has been most eminent as an astronomer. By means of a magnificent telescope at Hastings-on-the-Hudson—the grinding of the 28-inch object-glass of which occupied all his spare time for three years—and special spectroscopic and photographic apparatus of his own devising, Dr. Draper has been enabled to perform an extraordinary feat in spectroscopy—that of photographing a very large space of invisible lines in the ultra violet portion of the spectrum beyond the line H. He subsequently reproduced this appendage to the spectrum by the albertype process and published a pamphlet in regard to this very interesting subject, in which he gave the wave-lengths of all the principal lines. The pamphlet has attracted a great deal of attention among scientists in this country and in Europe, and it is considered one of the most remarkable contributions to the new and wonderful science of spectroscopy. He took an important part in the observation of the transit of Venus in 1874, and of the great solar eclipse of 1878.

The discovery of oxygen in the sun in 1877 was Professor Draper's greatest work. He published a paper on the subject, and had the photograph which he made of the oxygen line in the solar spectrum lithographed. His paper was translated and published in the German and French journals. The discovery met with much opposition abroad, and Professor Draper went over and explained the matter more fully. After he had convinced scientific men in London and Paris that his conclusions were based not on mere opinion, but on exhaustive experiments, he was received with great enthusiasm by them and his new theory of the solar spectrum was acknowledged to be the true one. He used in making this now famous discovery a Rutherfurd reflection grating of 17,296 lines to the inch. Mr. Lockyer suggested the use of such an instrument in observing a solar eclipse, but had been anticipated by Professor Draper, who had, several months before Mr. Lockyer's paper was presented to the Royal Society, constructed his phototelespectroscope.

The commissioners appointed by Congress to observe the transit of Venus on December 9, 1874, selected Professor Draper as the Superintendent of its Photographic Department. In this capacity he had such marked success that a gold medal was struck for him at the Philadelphia Mint, by order of Congress. The medal bears the following inscription in Latin: "He adds lustre to ancestral glory."

The cause of his death was pleurisy, and his illness was very brief, for as late as the Wednesday evening of last week he entertained the members of the National Academy of Sciences, over fifty in number, at a dinner given at his house. He had felt slightly unwell in the evening, and at the table those near him observed before the dinner was over that he was in pain. He made light of it, however, and said that a hot bath would soon bring him out all right again. But it did not, and shortly after midnight a physician was summoned. Acute pains in his chest continued with increasing severity until he died, on Monday morning at ten minutes before 4 o'clock. His sufferings were very great, and much of the time he was kept under the influence of morphia on account of the excruciating pain. He realized that he might die from the attack early, but he did not entirely give up hope of recovery until Sunday night, when he said to Dr. Metcalf, his physician: "Well, I've fought bravely, but they've got the best of me. I must go." Shortly after this he died. It is believed by his physicians that he brought back the seeds of the disease in a bad cold contracted on his last visit to the Rocky Mountains and that the state of his system was such as to make the end almost certain from the beginning.

—— DR. DANIEL W. CULYER, a prominent practitioner of Jersey City, dropped dead while hunting near Deckertown, N. J., on November 15th. The cause is supposed to have been cardiac disease.

—— On Nov. 1st, GEORGE CRITCHETT, F.R.C.S., in the 66th year of his age. Mr. Critchett commenced early in his career to devote especial attention to ophthalmology and enjoyed a wide reputation as a successful and skilful operator. He introduced several new methods into practice, and was the author of numerous valuable contributions to ophthalmological literature.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 13 TO NOVEMBER 20, 1882.

MOORE, JOHN, *Surgeon.*—The leave of absence granted by S. O. 145, C. S. Department of Colorado, extended one month.—*S. O. 175, par. 2, Military Division of the Pacific, November* 3, 1882.

WILLIAMS, JOHN W., *Major and Surgeon.*—Assigned to duty at Fort Coeur d'Alêne, Idaho.—*S. O. 161, par. 3, Department of the Columbia, October* 26, 1882.

GARDNER, EDWIN F., *Captain and Assistant Surgeon.*—Ordered to Fort Walla Walla for duty.—*S. O. 161, par. 3, Department of the Columbia, October* 26, 1882.

REED, WALTER, *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the East, and assigned to duty in the Department of the Platte.—*S. O. 266, par. 4, A. G. O. November* 14, 1882.

OWEN, WM. O., JR., *First Lieutenant and Assistant Surgeon.*—To proceed to Astoria, Oregon, and report to First Lieutenant E. B. Rheem, Twenty-first Infantry, for duty with his command.—*S. O. 164, par. 5, Department of the Columbia; October* 30, 1882.

WYETH, M. C., *First Lieutenant and Assistant Surgeon.*—To report to Fort Snelling, Minn., for temporary duty.—*S. O. 185, par. 3, Department of Dakota, November* 9, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL LECTURES.

TYPHOID FEVER.

A clinical lecture delivered at the Charity Hospital, New Orleans.

BY S. M. BEMISS, M.D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE, UNIVERSITY OF LOUISIANA.

(Reported by J. H. BEMISS, M.D., from clinical notes by DR. T. D. FITCH.)

GENTLEMEN: I desire to call your attention in this lecture to two cases of typhoid fever, the clinical careers of which you have recently had an opportunity to witness. Typhoid fever is not a very common disease in this city; and as rich as this great hospital is in furnishing examples of all forms of disease that the physician is called upon to treat, it has been very seldom indeed that I have been enabled to exhibit two cases of typhoid fever under treatment at the same time. I must further state that when such occasions do occur, they are generally brought about by the simultaneous arrival in this city of the subjects of the disease, coming from localities where typhoid fever is more an endemic affection than it is here.

Typhoid fever is, as most of you are aware, one of those affections that we classify as filth-diseases. This term may be regarded as especially applicable to typhoid fever, since it is well understood that the specific cause which produces the disease may be conveyed to the systems of the well by the fecal matter of those sick with the malady. Again, it is also well understood that this specific poison is rendered more intense in its toxic effects by combinations with extraneous filth. Thus in a two-fold sense it may be called a filth-disease.

This special poison which produces typhoid fever is conveyed into the system by means of substances taken into the stomach; for example, water and milk; and under some circumstances may be rendered capable of being air-borne and be brought into the human system by way of the respiratory apparatus, or by effecting lodgement upon the mucous membrane of the mouth or pharynx. The best accepted doctrine is, that in becoming an air-borne agent, so as to transmit the disease through this medium, the stools containing the poison must become desiccated and distributed through the atmosphere in the form of dust. New Orleans is not so circumstanced as to favor either of these methods of distributing the typhoid fever poison. We obtain our drinking water from wooden cisterns filled by rain-water falling upon the roofs of houses. This method of obtaining drinking water cuts off all danger of spread of typhoid fever through those means by which it is so commonly diffused in localities where the drinking water is obtained from wells or natural fountains. In those localities, the stools of persons sick with typhoid fever may find their way through surface or sub-soil water to those sources of water supply to which the inhabitants are confined. Here, on the contrary, if the filth which contains the poison should render our water impure, it can only do so by first becoming desiccated and then finding lodgement in the shape of dust on the roofs of our houses and being washed by rains into our cisterns. This explains, and in so far as I know, it is the only adequate explanation of the fact, that New Orleans has never experienced an epidemic of typhoid fever. We must, however, deplore the fact that no similar statement can be correctly affirmed in respect to the greater number of the cities and towns located in the Mississippi valley. It is well to call your attention in this connection to the entire disregard of all sanitary precepts and sanitary experience, which is observable in the location and construction of both our towns and family residences. We generally find them located near a natural fountain of water which is usually situated in a depression of the earth's surface. As a general rule, privies are not provided with boxes, nor even with pits, and the consequence is that with every shower the fecal deposits are washed along the surface and find their way into the drinking water of the people.

I will, therefore, without further digression, call your attention pointedly to the histories and clinical phenomena of the two cases referred to. In the course of rehearsal of these symptoms and histories, or at the close, I will introduce such comments as seem apposite.

The first of these patients, in the order of their admission to the Hospital, was James Sentenn, aged 16 years, a native of New York. He was admitted to Ward 18, bed 254, November 29, 1881. He had just reached New Orleans on the day of his admission, having made the voyage from St. Louis in a flat-boat. He states that he had been sick about a week before reaching the city.

November 30.—I saw the patient for the first time on the morning of November 30. The house-surgeon had given on the evening of the 29th ℥j of the liquor cinchonidia of the hospital, which contains grs. v of sulphate of cinchonidia dissolved by means of dilute sulphuric acid. I prescribed on this visit ℥ss of the same, to be given in ℥j doses every four hours; also directed that bitartrate of potassium should be given in ℥j doses every three hours, in lemonade. Epistaxis had occurred just prior to my visit, and there was evident tendency to diarrhœa.

December 1.—Patient complained of abdominal pain; had again had epistaxis; skin dry, cheeks flushed. Ordered

℞.—Neutral mixture, ... ℥iiiss.
Tinct. digitalis,
Syrup morphia, ... āā ℥ij.
M. et. ft. sol. Sig. Tablespoonful every two hours.

Also a diet of beef tea alternated with roast apple and boiled milk.

2d.—Epistaxis had again occurred; abdominal pain still troublesome. Ordered

℞.—Neutral mixture, ... ℥iij.
Tinct. hyoscyamus,
Tinct. digitalis,
Syrup morphia,
Syrup ipecac, ... āā ℥ij.
M. et. ft. sol. Sig. Tablespoonful every four hours.

Diet of milk and beef tea.

Student reported that at evening visit the patient was delirious, and had had about fifteen liquid stools of a yellowish color.

3d.—Epistaxis again, and continuance of abdominal pain. Bowels still loose; stools pea-soup in character. Treatment continued.

4th.—Patient delirious all night. Epistaxis, and, when rational, persistent complaint of pain in abdomen. Treatment continued.

ending N
amo·

5th.—Bowels still loose; stools pea-soup in character; no epistaxis; still complains of pain in abdomen; distinctly marked rose-colored spots on abdomen; tongue brown, dry, and cracked. Thermometer could not be placed in mouth because of delirium. Ordered

℞.—Sulphuric acid dil., ... ℥j.
Tinct. cinchona co., ... ℥vij.
Syrup morphia, ... ℥iv.
M. et. ft. sol. Sig. Teaspoonful every four hours.

Bowels still loose. Ordered that chloral hydrate ℈j be given at night in case of insomnia.

6th.—Large number of rose spots have appeared this morning; tongue coated brown; abdomen tympanitic. Had taken the chloral hydrate as directed, and several hours of good sleep ensued. Treatment continued.

7th.—Student reported that at his last visit on the previous evening, the patient was found in a semi-comatose state; eyes partly closed; mouth open, breathing stertorously; some new rose-colored spots; only one stool during the day; tongue dry, brown, and cracked on each side; had not passed urine during the day; urine drawn off with a catheter; patient so nearly unconscious he scarcely noticed its introduction. Patient was found this morning in a state of coma-vigil; abdomen tympanitic; tongue brown, cracked, and red at tips and edges; also sudamina present. Had taken chloral hydrate grs. xx per rectum; bladder was emptied by means of catheter. Treatment continued. Concentrated animal nourishment in fluid form was pressed upon the patient by mouth and rectum.

8th.—Mr. Fitch reports that at his last visit the evening previous the patient had had one stool only during the day, somewhat moulded in character, and had passed a little urine at the same time. Subcrepitant and sonorous râles over base of posterior parts of both lungs, with expectoration of yellowish sputa. Patient had taken chloral hydrate grs. xx, per rectum, succeeded by several hours of tolerably comfortable sleep; had one stool in night, one in morning, somewhat moulded and clay-colored; has passed sufficient quantity of urine; tongue brown, dry, and cracked. Patient took oatmeal and boiled milk and some wine. Medicines continued.

9th.—Student reports three stools during the previous day, somewhat moulded and clay-colored. Had taken as nourishment oatmeal and chicken-broth. Was found to have rested badly during the night, although chloral hydrate had been given as usual. Had one liquid stool during the night. More disposition to eat.

10th.—Patient had had six stools during the latter part of previous day; appetite not so good; tongue still coated brown; had rested pretty well during the night without any hypnotic.

11th.—Had been delirious all night; tongue brown-coated; teeth covered with sordes; one loose stool. Ordered, Dover's powder, grs. x, at night; diet of wine, milk and crackers, and chicken-broth.

12th.—Had had three stools during latter part of the day before, moulded and darker in color. Slightly delirious this morning; tongue brown-coated; abdomen not so swollen and tympanitic; disposed to eat. Ordered repetition of Dover's powder at night. More rational.

13th.—Bowels not moved since yesterday morning; rose spots gone; somewhat delirious last night. Took Dover's powder as directed.

14th.—Had had two stools; restless and somewhat delirious at night; picking at bed-clothes. Bed-sore over the sacrum. Tongue somewhat moist and shows a disposition to clean. Medicines continued.

From this time on, convalescence progressed without interruption until on December 21st, and about the thirtieth of his disease, he was discharged from further treatment. He was, however, kept in the hospital under observation until sufficiently strong to admit of his discharge.

The second case was that of Frank Boyer, aged 18 years, native of Ohio, who was admitted to Ward 20, Bed 298, on December 3, 1881. Patient had been travelling with a circus company. Stated he had been sick an indefinite length of time; did not know how long, nor where he was when he first began to complain. Entered with a flushed face, fever, diarrhœa, and complained of pain in back.

December 4.—Had been given ℥ij[1] Hauster's cinchonidia during the evening of the 3d of December by the house surgeon. Had had one liquid stool during the night. Ordered ℥j of H. C. every three hours.

5th.—Treatment continued.

6th.—Well-marked rose spots observable upon the abdomen; no pain, but lies with knees flexed; face flushed; vomited three times; complete anorexia; skin moist.

7th.—New rose spots observable; one stool resembling pea-soup; face flushed; some tympanitis and tenderness in iliac region.

8th.—One characteristic typhoid stool; new eruptions; gurgling in ileo-cæcal region; tongue brown-coated; face flushed and red.

9th.—Three characteristic stools since last observation; a few new eruptions; gurgling in ileo-cæcal region; tongue coated brown; patient is slightly deaf.

10th.—Patient delirious during the night, but complains this morning of pain upon pressure in ileo-cæcal region; headache; deafness; three stools since last report, still characteristic.

11th.—Four stools, somewhat more consistent; tongue the same as before reported; gurgling in ileo-cæcal region; patient slightly delirious.

12th.—No stools since last report; tongue brown-coated; sordes upon the teeth; delirious and attempting to leave bed.

13th.—One stool since last observation, probably induced by rectal injection of grs. xx of chloral hydrate in sweet milk. Patient restless during the night; abdomen tympanitic; tongue brown-coated; not so delirious to-day, but is still deaf.

14th.—No stools since last observation. Retained an enema of chloral hydrate, grs. xx, in milk. Much grinding of teeth at night, but not delirious; some deafness yet; perspired freely; tongue brown-coated.

15th.—No stools since last observation; tongue moist and cleaning. Very little delirium during the night.

From this time on, patient continuously improved, until the morning of December 22d, when he was discharged from treatment, but retained in the hospital until convalescence was perfected.

Having now rehearsed the leading clinical events of these cases with sufficient minuteness to give you a clear impression of their symptomatology, let me ask your attention to the *diagnosis* which has been announced. In other words, are the proofs unquestionable that the patients were really sick with typhoid fever? The diagnosis which has been given you is perfectly defensible in regard to each case.

1st. The symptoms relating to the nervous system—(a) ataxia, (b) delirium, (c) coma-vigil, (e) deafnesss—are clearly illustrative of typhoid fever.

2d. The characteristic march of temperature.

3d. The epistaxis.

4th. The diarrhœa with the (a) characteristic stools, and (b) gurgling in the ileo-cæcal region.

[1] Similar solution to liquor cinchonidia with the addition of 7½ drops of tincture of opium to the ℥.

And last of all: 5th. The typhoid roseola quite surely demonstrate that we had to deal with that disease.

Another question which naturally occurs to the physician of long practice in this part of the world, where malarial affections are so common, is whether the typhoid fever was uncomplicated in these cases. I have been able to show you in the wards of the hospital this winter, cases which presented the clinical phenomena of a pathology compounded by the co-existence of the malarial and typhoid fever poisons in the same person. In a future lecture I hope to demonstrate these cases, so as to point out the differences in their clinical courses as compared with the two cases which form the subject of this lecture. For the present, I can state that there were no evidences going to prove that these cases were complicated by the presence of any other specific poison than that of typhoid fever.

I hope, during the present course of lectures, to impress your minds with the importance of cultivating more precision in language in the use of the term *typhoid* in reference to any disease, than is generally employed in medical conversations, or even in some medical writings of the present day. We may properly speak of a patient sick with any form of disease as being in a typhoid state or condition. Here we use the term in its strictly adjective sense, but to speak of typhoid fever substantively, should convey to your mind the idea of a patient suffering from the effects of the specific typhoid poison. A malarial case which has fallen into a typhoid condition is not typhoid fever, and the term typho-malarial should be restricted to those cases in which the typhoid fever poison and the malarial poison are each present, and each pursuing its own morbid process and giving rise to its own symptomatology.

The morbid process of each of the two cases brought up before you seems to have been essentially that of typhoid fever. In the first place, we observe a general or constitutional effect of the poison in the occurrence of ataxia, feverishness, and epistaxis (in one case) as very early manifestations of the disease. I think the proofs are quite conclusive, that there is a general or constitutional effect of the typhoid fever poison before any symptoms are observable which indicate the production of its local lesions. Again we may say that while these constitutional effects, if such are produced, seem to antedate the occurrence of local lesions, it can also be stated that they bear no direct relation, in gravity, to the extent or severity of any local lesions which may subsequently occur. In respect to the febrile march, which is so characteristic of typhoid fever, it must be admitted that even if the feverishness which marks the early stages of the disease is an essential fever, *i. e.*, a fever produced by the action of the typhoid fever poison upon the heat-making processes by some influence exerted through the blood, the more intense fever which marks the fully declared disease does bear a direct relation to the progress and various stages of the local lesions. Before the first ten days of typhoid fever have elapsed the temperature begins to show a regular diurnal increase which observes a close co-relation to the progress of the intestinal lesions. When the temperature has reached its highest figure, it maintains itself very nearly at this stadium until the process of ulceration has come to a stop. Then we have oscillations of temperature exhibiting a close resemblance to those which occur in the hectic of phthisis, or other pyogenic conditions of disease. I think, therefore, that it may be safely affirmed that the typhoid fever poison has one effect upon the system which is general, and seems to be primary or essential; and another effect which is local, and which in order of sequence succeeds its primary effect.

It is always profitable to the practitioner of medicine to be conversant with the various modes through which any given disease ordinarily produces death. This is equivalent to that understanding of the strategy of an enemy which frequently gives the general his success. Death in typhoid fever cases most frequently occurs from:

1st. Exhaustion; there are four factors which concur in producing death in this manner:

a. The changes in the blood primarily induced by the poison.

b. The unusual high markings of the fever curves.

c. The excessive diarrhœa.

d. The damage to the digestive processes by reason of the lesions of the alimentary canal, and the consequent anorexia.

2d. Hemorrhage is also a mode of death by this disease. Hemorrhage sometimes occurs within the first ten days of illness from:

a. Congestion and breaking down of the capillaries in the mucous and sub-mucous tissues which are the seat of inflammation induced by the typhoid deposits.

b. When hemorrhage occurs during the third week of disease it is more apt to be due to the erosion of bloodvessels by the process of ulceration.

3d. Perforation is also a late event in the course of the disease, and in truth sometimes takes place after convalescence has seemed so complete that the patient has been discharged from observation.

4th. It should also be remembered that certain fatal sequelæ are liable to befall typhoid fever patients after the disease has run its course; for instance—

a. Heart failure in consequence of degenerative changes in its muscles; also

b. Diseases of the lungs, as pneumonia and tuberculosis.

The prognosis in typhoid fever must be based principally on the greater or less urgency of those symptoms which presage the occurrence of exhaustion. Great nervous ataxia, delirium, sinking in bed, insomnia, profuse exhaustive diarrhœa, incompetency of the nutritive processes, are unfavorable prognostics.

No specific treatment of typhoid fever can be formulated so as to be particularly gratifying to the practitioner of medicine, either as respects the soundness of the philosophy upon which it is theoretically based, or the results which it affords. Everywhere, and in all ages, the medical history of mankind appears to show some prompting in the direction of a specific for each of the maladies which afflict the race. The therapeutics of typhoid fever show a long list of remedies which have been suggested as possessing special efficacy in effecting its cure. I do not consider that it will be profitable to occupy your time in recapitulating the list of remedies which have been resorted to as specially curative of the disease. In looking over them you will find that, for the most part, each one was supposed to have reference to some particular phase or type of the morbid phenomena present. For example, yeast and charcoal, bicarbonate of sodium, and chlorate of potassium have been frequently used for their supposed antagonism to the septic nature of this disease. Iodine may possibly be classed in the same category. The calomel treatment, which has enjoyed so much reputation, is based upon its influence in antagonizing inflammation of solid structures and in eliminating by reason of its cathartic effect.

Typhoid fever has never under my observation been jugulated by any form of treatment which I have seen instituted. But notwithstanding the truth of this affirmation, we must admit that cases which cannot be otherwise diagnosed than as typhoid fever, do occasion-

ally terminate so easily and so suddenly, that we call them aborted cases.

These admissions in regard to our incapability of aborting typhoid fever, or curing it by any one specific remedy, need not dishearten us. There is a rational method of treatment, by which we can conduct a very large percentage of our patients through the dangers of an attack. I will as briefly as possible lay before you those methods of treatment which are regarded as productive of the most favorable results. As the measures of treatment differ in the various stages of typhoid fever, it will in all probability instruct you better, if, in speaking of any remedies considered to be indicated, I should at once give you my estimates of their methods of use and beneficial results throughout the clinical course of the disease.

As the fever is always an early and very important symptom in typhoid fever, let us first consider the antipyretic treatment of the disease. The application of cold to the surface is a very old form of practice for the reduction of temperature in this fever. This may be practised by means of cold baths to the whole surface, repeated as often as reaction occurs after their use; or cold sponging; or the applications of ice. This method of practice is applicable to cases in which the heart's action is vigorous and the surface warm; if there is a feebly acting heart, or if hemorrhage is threatened, it is inadmissible. Cold drinks, in sufferable quantities, are never objectionable. Injection of cold water in large quantities into the lower bowel is also a measure by which systemic heat can be certainly reduced.

Quinia in large doses is highly spoken of by continental physicians of Europe as an antipyretic agent. In order to obtain its good effects, it must be given in doses of ℈ij or more in the space of an hour. I have never practised this heroic administration of quinia for the purpose of reducing temperature, and can add nothing from my own observation to the testimony of those physicians who advocate it. It is very rarely that I have ever treated a case of typhoid fever in which I have not given quinia to the extent of ℈j or ℈ij within the first hours of treatment, for the purpose of eliminating whatever malarial pathology might be supposed to complicate the case. Later in the disease I have often given quinia during the oscillations of temperature which mark the later periods of the affection, both for the purpose of obtaining its tonic effect and also its probable good effect as a local antiseptic upon the ulcerated intestines. If the stomach does not tolerate quinia, its solution, if properly prepared, is generally retained and absorbed by the rectum. I have only further to say in regard to quinia that it is better borne by young persons than by adults, and, under my observation, is more likely to be followed by good results.

Diarrhœa is another symptom of great importance, and is seldom absent from cases of typhoid fever. It manifests itself during the first week of disease, or as soon as a hyperæmic condition of the intestinal coats of the bowels is induced by the typhoid infiltrations. In this stage of the disease it is very often advantageous to the patient to suffer the diarrhœa to go on unchecked. There are, however, cases in which this symptom is so aggravated and excessive in quantity during the first stages of the disease that it would be unwise practice to allow it to go on without interference. The practitioner must in each case exercise his own judgment as to the course he will pursue with reference to the diarrhœa. My own rule has been to endeavor to ascertain—first, if the stools are attended with a sense of relief to the patient; next, as to the amount; and, lastly, as to the condition of the patient as respects his strength and apparent capability to endure their persistence. If the stools are not exhausting, it is better for the first week of disease that they should not be too violently checked. Leaving out of view the question of elimination of the typhoid fever poison by means of the stools, so as to rid the patient of an amount of free poison in the intestines which would be subsequently absorbed, there can be no doubt that the diarrhœa does tend to relieve the hyperæmia and inflammation of the affected bowel. It seldom becomes necessary to urge the bowels to any action additional to that common to the disease. But I have nevertheless seen cases in which the administration of castor oil in teaspoonful doses every two to four hours seemed beneficial. I have, however, more often secured whatever benefits were to be derived from increasing the evacuations by large injections of water into the rectum; these injections to be given cold, provided the fever was intense. But, as a rule, the physician's energies are required to be directed to the limitation or arrest of the diarrhœa instead of its promotion. For this purpose we have nothing which can be substituted for opium. This may be given by the mouth, associated or not with an astringent; or it may be given by rectal or subcutaneous injection.

Hemorrhage is another symptom of great importance in typhoid fever. If it occurs in the first ten days of the disease, the probabilities are, as previously stated, that it is from the broken-down capillaries in the hyperæmic intestinal canal. Under these circumstances there is little danger of its becoming excessive, and physicians may trust its relief to ergot, in combination or not with some astringent, *e. g.*, gallic acid. In the latter stages hemorrhage is not infrequently a dangerous symptom, and physicians should endeavor to arrest it by more energetic practice. Gallic acid in camphor water may be given, five grains every second or fourth hour; or acetate of lead may be used. In either instance applying cold over and above the ileo-cæcal region should be resorted to. At the same time morphia may be administered by hypodermic or rectal injection. Long since, my experience taught me that intestinal hemorrhage, if properly and timely treated, was not so disastrous to life as it was once supposed to be.

Perforation is fortunately a rare event in typhoid fever. When it does occur, a fatal result is probably inevitable. My own opinion has been, that the very few instances in which recovery has occurred after supposed perforation have not, in reality, been instances in which that accident did occur, but only cases in which a suppurating gland had ruptured into the peritoneal cavity. In all cases where perforation has been diagnosed, the only treatment left us is large opiates, absolute rest, and the administration of liquid nourishment in small quantities frequently repeated.

The perturbations of the nervous system are important events to the practitioner who has care of a case of typhoid fever. The delirium of the first ten days may be alleviated by cold applications, or even in some instances by cutting the hair and the application of ice to the scalp, and the administration of bromide of potassium, or chloral hydrate. Later in the progress of the disease delirium is a more important symptom, and is due either to exhaustion, the accumulation of secondary poisons in the system the result of increased metamorphosis, or the interference with nerve function by the persistently heated blood. Insomnia and that marked form of insomnia called coma-vigil almost invariably accompany the delirium of this stage of the disease. It is of great importance that they should be relieved as promptly as possible. It may safely be asserted that if the physician regards the insomnia as the feature of these troubles which is first to be antagonized, he meets the chief indication. For this purpose we have a precious remedy in chloral hydrate.

This may be given in doses of ℈j or ℥ss, or even ℈ij, if the indications are urgent, either by mouth, or by rectal injection, dissolved in milk or suspended in beef-tea. Opium or bromide of potassium may be added to it if necessary, but I have generally found that chloral hydrate is sufficiently effective without the co-operation of other drugs. Dover's powder given in doses of grs. x, at night, often produces a very desirable effect.

You will observe nothing in this lecture in regard to the treatment of typhoid fever by means of mineral acids. I must, however, admit that within the last fifteen years I have scarcely treated a patient to whom I have not given one or more of these acids. Preferably I have used sulphuric acid, but occasionally nitro-hydrochloric—in every instance diluted—in the early stages of the disease, combined with ipecac, but in the stage of ulceration and cicatrization, combined with quinia or the tincture of cinchona; and frequently with tincture of opium. It is probable these acids may exert a beneficial local effect upon the inflamed intestine and may also further the digestive processes. But I reject the theory that they are beneficial because of any alkalinity of the system supposed to be peculiar to the disease.

Neither have I called your attention to certain symptoms, which, although considered of minor importance, so far as life is concerned, are still exceedingly troublesome both to patient and physician. One of these is tympanitis. For the relief of this I have generally resorted to injections of asafœtida in water or milk, and to turpentine stupes, and sometimes cold applications externally to the abdomen. Turpentine may often be given internally with decided benefit. I must, however, in this connection, take occasion to warn you against falling into the custom so common in the South, of resting the treatment of typhoid fever upon the persistent use of turpentine. A few doses of gtt. xx in emulsion and repeated not oftener than every third hour, constitute the limits of my administration of turpentine in the recent years of my practice.

Hiccough is another annoying symptom, sometimes indeed representing the last straw upon the camel's back. Bromide of potassium, chloral hydrate, belladonna, and camphor, and blisters to the epigastrium constitute the remedies upon which I have principally relied.

Bed-sores should be anticipated as far as possible by changing the points of pressure, and rubbing the endangered parts with alcohol, camphor, or arnica.

It would seem scarcely necessary to admonish you that attention to the nutrition of a typhoid fever patient is equally important with his medicinal dosing. For the first week of the disease, patients for the most part, may be fed upon farinaceous articles and digestible fruits and milk. A very agreeable article of diet to most patients is the traditional roasted apple and milk, sometimes to be rendered more palatable by the addition of a small quantity of sugar. As soon as the diarrhœa becomes a prominent event and the patient's condition becomes more ataxic, we must resort to concentrated animal food given simultaneously with farinaceous articles, as oatmeal and maize, or given separately at alternate intervals.

Failure of the heart, as evinced by weakened pulse or cooler surface, calls in the most decided manner for alcoholic stimulants. In truth the wise physician does not wait for evidences of a failing circulation to become strongly marked, before resorting to stimulants. I can certainly say that while I may have occasionally felt regrets that I had not earlier begun with alcoholic stimulants, I can not recall a solitary instance in which their administration has been injurious in any stage of the disease, or during any state of exalted temperature.

One additional precept in regard to the administration of alcoholic stimulants and food to typhoid fever patients is proper to be pressed upon you. This is, never to allow intervals between giving food and stimulants to your patients, to be extended by a longer period than three hours at furthest. Consequently in those conditions which are termed coma-vigil, food and drinks must be placed upon the patient's tongue at intervals of two to three hours, preferably the former. If the patients are much exhausted, they must be awakened from sleep to take nourishment and stimulants. Cold drinks in some agreeable form should be frequently given to a typhoid fever patient, from the beginning to the conclusion of an attack. These may consist of ice-water, lemonade, iced tea, apollinaris water, or, in the latter stages, barley-water or decoctions of rice.

The rooms of typhoid fever patients should be kept well ventilated, and the clothing and bedding frequently changed. The hair had better be cut short at the commencement of the affection. The surface should be frequently sponged with cold or tepid water, as may be most agreeable to the patient.

The stools should be so treated as to prevent the communication of the disease to other persons. They may be treated with sulphate of iron, or chloride of zinc placed in the bottom of the vessel, or they may be mixed with sawdust and burned; or they may be buried in the ground in some situation where all danger of doing mischief shall be prevented.

Convalescence should not too hastily be said to be confirmed in a case of a patient recovering from typhoid fever. Such accidents as perforation of the intestine and paralysis of the heart, have carried off patients who had been dismissed from treatment and observation.

THE VESICULAR AND BULLOUS FORMS OF ERYTHEMA EXUDATIVUM MULTIFORME.

By I. EDMONDSON ATKINSON, M.D.,
PROFESSOR OF PATHOLOGY AND CLINICAL PROFESSOR OF DERMATOLOGY IN THE FACULTY OF PHYSIC, UNIVERSITY OF MARYLAND.

It is one of the great merits of modern dermatology, that it has simplified the study of skin diseases, both by the recognition of bonds of pathological relationship between a number of apparently dissimilar manifestations of disease and by the consequent adoption of much less complicated systems of nomenclature. With the older writers the tendency was to see in each separate lesion a distinct disease, and dermatological literature was thus saddled with a confounding multiplicity of terms, while the so-called individual diseases were, in many cases, so inextricably blended, that the closer attention the student lent to their investigation, the greater was his confusion. When, therefore, it became evident that many processes that may exhibit dissimilar clinical histories and a variety of lesions, may possess a pathological unity, an immense advance was made. Not to speak of eczema, that veritable dermatological Proteus, and acne, an example of this variety of lesions is shown in erythema multiforme. Diligent clinical observation has shown that a series of morbid manifestations, beginning with simple redness and extending through the development of papules, tubercles, vesicles, and even blebs, are all connected in a closely related group, to which the name of erythema exudativum multiforme was first

given by Hebra, and which is now universally adopted.

At present, as sub-varieties of erythema multiforme, are included E. papulatum, E. tuberculatum, E. annulare, E. iris, E. marginatum (E. gyratum), E. urticatum, E. vesiculosum, E. bullosum, Herpes circinatus, and H. iris. There are here collected a series of morbid processes, the nature of which, as yet not accurately determined by microscopical investigation, clinical observation shows to be essentially identical. These different forms may blend and show all degrees of transition among themselves; they also occasionally develop transitional phases with cutaneous affections of confessedly different nature. We thus find erythema multiforme in its urticate variety exhibiting relations with urticaria, in its bullous variety, resembling acute pemphigus in its papular and tuberculated and annular varieties and when extravasations occur, merging into purpura rheumatica. This blending of the characteristic features of erythema multiforme with those of other and usually unrelated affections indicate that in cutaneous pathology, as in every other department of natural science, hard and fast boundary lines do not exist, one form of disease imperceptibly blending with another; and that our nomenclature is devoted, for the most part, to types, the limits of which pass by easy grades into each other.

Erythema exudativum multiforme, as ordinarily understood, is "a skin affection which appears with, but more commonly without, fever, in the form of bright or dark-red, disseminated or thickly clustered efflorescences, either flat or studded with central papules. It always originates as an inflammation, appears in the form of spots, papules, or tubercles as large as lentils or hazel-nuts, and is accompanied by slight itching, burning pain, or a feeling of tickling. The efflorescences are almost always situated upon the backs of the hands and feet, upon the arms and forearms, the legs and thighs, more rarely upon the body and face, exceptionally upon the throat, scalp, and ears. They either fade without scaling, or slight desquamation or pigmentation develops. The erythema comes preferably in youth, seldomer in later life." (Neumann, *Lehrbuch der Hautkrankheiten*, 1880, p. 158.) It must be distinguished from erythema from simple hyperæmia.

If the eruption consists of papules, bright red or bluish in color (from extravasation of blood), somewhat flattened, and fading after a week or ten days or longer, it is called *erythema papulatum;* if of larger papules or tubercles, *erythema tuberculosum;* if the papules fade in the centre, becoming pale or bluish, while the peripheral portion remains or extends, it is called *erythema annulare;* if new circles appear within the first-formed circle, or if varying shades of coloring are left by the fading lesion, it is called *erythema iris;* if two or more rings thus formed coalesce, the condition is known as *erythema gyratum;* if the lesions resemble the wheals of urticaria, as sometimes happens, it is called *erythema urticatum;* if the exudative process is very acute and intense, so that small vesicles are formed upon the lesion, the condition is termed *erythema vesiculosum;* and if the central portion becomes depressed and dries, the vesicles form a circle constituting ordinary *herpes circinatus;* should one or more circles of vesicles form within the original one and form centrifugal layers of vesicles or crusts, it is called *herpes iris;* where the small vesicles are replaced by large blebs, *erythema bullosum* is recognized. While these modes of manifestation constitute non-essential variations of the same pathological process, we occasionally encounter them as complications of other disorders, or as forming stages of transition. Not very unfrequently one is perplexed in determining whether given cases represent phases of erythema multiforme, or of urticaria, purpura rheumatica, ringworm, and even pemphigus acutus.

I propose in this paper to direct attention to some of the more obscure varieties of erythema multiforme, especially as exhibiting in some part of their course, sub-epidermic collections of fluid, constituting vesicles, and even blebs. As showing transitional stages between erythema annulare, or iris, and herpes circinatus, the following case is related:

Case 1.—Mary R., 18 years old, a housemaid, of Irish parentage, applied for treatment February 24, 1876. She had an eruption that had made its appearance about the preceding Christmas. Her general health was excellent, and the eruption was the only disorder complained of. This was confined to the forearms, hands, and dorsal surfaces of the feet, and exhibited various stages of evolution, affording excellent opportunity for studying the course of the lesions. These began as minute, pearl-like papules, very itchy, situated upon small red areolæ, and of pinhead size. Within twenty-four hours the papules became larger, and their summits depressed, so that the effect of an elevated ring of eruption was given. The central depressions were often the seats of a slight serous discharge, which ceasing, the lesion gradually faded away, new lesions, however, constantly appearing. These lesions would not exceed in size the diameter of a small button, and in their stages of highest development exhibited the color characters of erythema iris. For example, there would be a red areola, within which was the annular elevation, paler in color and slightly resembling an urticarial wheal, while the color of the dusky centre gradually lost its hyperæmic redness and slowly faded, with desquamation. While this was the type of the prevailing form of eruption, there were scattered lesions that enabled one to perceive that the cause of the pearly color of the rings was serous exudation in the deep epidermic layers. Thus, flattened vesicles could be occasionally detected, the eroded summits of which discharged a thin, serous fluid. The peripheral extension of these lesions converted them eventually into flattened disks, exfoliating their scales from their pigmented surfaces. The patient was directed to take 7½ minims of Fowler's solution of arsenic, thrice daily, well diluted with water, after meals. Under this treatment the symptoms rapidly improved, but relapsed upon March 16th; and again April 22d, each time rapidly disappearing under the administration of arsenic. In the later attacks the lesions attained a diameter of one centimetre.

This case evidently closely resembled a case re-

lated by Mr. Jonathan Hutchinson in the "Descriptive Catalogue of the New Sydenham Society's Atlas of Portraits of Diseases of the Skin," part ii., page 71, and depicted in plate xxiv. My next case was somewhat similar, although the lesions were more unequivocally vesicular.

CASE II.—Thomas F., a young mulatto, laborer, 28 years old, came under treatment Jan. 29, 1876. Early in December the present eruption had appeared, first upon his hands (palms and dorsal surfaces) as little papules and vesicles. The eruption had been constantly renewed by fresh lesions, and upon his person, at his first visit, all stages of its course were represented. At scattered intervals, especially over his legs and arms, were large vesicles and small blebs or their remains. The true relationship of the lesions was revealed by a study of their symptoms. Upon the hands, for example, especially the palms, there were a number of spots, slightly elevated, and to the touch revealing infiltration and heat. These were as large as split peas, and when examined upon the pale-colored palms showed reddish areas inclosing slightly raised surfaces paler than the normal skin, while external to the reddened area were pale surfaces like urticarial wheals, but fading centrifugally (*erythema iris*). At their first appearance, these external pale elevations inclosed reddish spots which, themselves, did not have the raised whitened centres. As the spots grew older, they did not extend peripherally, but slowly faded, leaving brown desquamating surfaces. A decided tendency to chronicity was here present, as shown in the outbreak, which lasted nearly four months, almost disappearing under the administration of arsenic, but speedily reappearing when, as frequently happened, the treatment was neglected. A return of the eruption was observed the following October, which yielded promptly to the use of arsenic.

Cases such as the foregoing often offer great difficulties in reaching a correct diagnosis. Not unfrequently examples are observed where the lesions of erythema papulatum are so blended with bullous eruptions that one is enabled to recognize the relationship of the former eruption and erythema bullosum without difficulty. As an example of this may be briefly reported:

CASE III.—A young lady, stout and healthy in appearance, of slightly constipated habit, first noticed an eruption upon her skin in March, 1880. Since that time she had had it pretty constantly until I saw her, during the following September, when the eruption involved the face, neck, trunk, arms, hands (backs and palms), and feet, but not the thighs and legs, except about the ankles. The lesions began as small red spots, which rapidly became annular or circinate, and extended peripherally. Many of these rings were surmounted by vesicles and even blebs (*E. bullosum*), which were said at times to equal the size of plums. These vesicles and blebs never developed except *upon* the erythematous circles. Itching was not very intense, but burning pain was complained of. At the date of my first examination there were upon the neck and shoulders numerous narrow, bright-red, slightly elevated rings from 1 to 2 cm. broad (*E. circinatum*). Here and there clear, transparent vesicles were arranged in circles (*Herpes circinatus*). The eruption was said to be greatly under the influence of arsenic, and always disappeared when the patient was taking this drug, the object of her consultation being to secure, if possible, a remedy that would afford permanent relief. Some time previous to her visit to me, blebs had formed upon the soles of her feet, rendering her unable to walk. At my examination no blebs were detected upon the surface, but upon the fauces were vesicles of considerable size. The erythematous and vesicular lesions alone were visible upon the skin.

One cannot fail, in considering the history of this case, to be reminded of acute pemphigus, with which affection it undoubtedly presented close analogies. I think, however, that the true nature of the malady was indicated by the prevailing circinate lesions, and that the blebs were simply extreme examples of the lesions of erythema exudativum multiforme. This tendency towards more intense and rapid serous exudation is exemplified in the following case.

CASE IV.—Harry Gray, a very bright colored mulatto, 17 years old, slender, but fairly nourished, had had attacks of the present eruption during the preceding six years, at irregular intervals, but usually more severely in the spring. The present eruption appeared April 9, 1877. When seen by me, the following day, his face, neck, and portions of the trunk, were invaded by a multitude of vesicles, varying from the size of pinheads to that of peas, the smaller ones giving a rasping sensation to the finger. They were all situated upon erythematous bases, were discrete, not umbilicated, and dome-shaped. Upon the cheek a number of vesicles had developed in the form of a small circle. Upon the back of the hands and forearms, the eruption was papular. During the succeeding day, the lesions developed with great rapidity over the whole body, and many vesicles coalesced to form large blebs with clear, serous contents. Itching, which had been present at the outset, had now given place to intolerable burning, for which morphia had to be administered. At the same time there was mild, febrile movement with furred tongue. Already by the 11th, the intensity of the eruption had subsided and new lesions had ceased to appear. There was but little disposition towards rupture of the vesicles and blebs, and absolutely no moist discharge. The erythematous areolæ slowly disappeared and the bullæ and vesicles, while becoming turbid, became at the same time flaccid and shrivelled, finally collapsed, and formed light crusts. The papules upon the arms became more flattened and slowly subsided without pain or irritation. Recovery rapidly followed.

This case might have been mistaken for acute eczema or acute pemphigus. From the former it differed in the acuteness of the attack, the bullous character of the lesions, the failure to produce discharge and the rapidity of the recovery. Acute pemphigus has been made to embrace a variety of indeterminate conditions of bullous eruption, and, unquestionably, many such cases as the one I have

described have been classed as examples of this affection. Acute pemphigus is certainly exceedingly rare, and it is not impossible that most cases reported as of this disease may have really belonged to the series of affections classed under erythema exudativum multiforme, or unusual forms of several other diseases; and that acute pemphigus as a substantive malady has no existence. Beyond question the study of dermatology has been greatly simplified by such classifications as enable us to consider as parts of one essential process, the various lesions evoked in its course; and the recognition of the different degrees of alteration that may be produced, with their varying symptomatology, will greatly facilitate the work of the clinician and therapeutist, and offer a way out of many perplexing difficulties. The knowledge that erythema exudativum multiforme may manifest itself variously, and in one of its directions, by the symptoms of which I have been speaking, and that its range really includes several conditions formerly looked upon as distinctive maladies, at once places the clinician upon a firmer footing.

In conclusion, a few words concerning treatment will not be out of place. Ordinarily erythema multiforme runs through its course in from two to four weeks, and no special plan of treatment is known to uniformly effect a cure in less time than that. In the more chronic cases and especially in those more prone to relapse, and the unusual forms such as those reported here, the good effects of treatment may be expected with more confidence. I can with some degree of confidence assert, in confirmation of the experience of Hutchinson and others, that arsenic exerts a favorable action upon the course of the disease, securing a prompt subsidence of the lesions when administered in moderately liberal doses; indeed, improvement follows so promptly that it would almost seem to result from a specific action of the drug upon the morbid process. Unfortunately the improvement does not always remain permanent, and a premature abandonment of the treatment is pretty sure to be followed by a return of the symptoms, in those cases where the eruption tends to become chronic.

TWO CASES OF CEREBRO-SPINAL FEVER, WITH REMARKS ON THE ETIOLOGY, DIAGNOSIS, AND TREATMENT.

BY JAMES C. WILSON, M.D.,
PHYSICIAN TO THE HOSPITAL OF THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THESE two cases, seen in private practice, have suggested to me several points of interest. Reports of single cases or of small groups of cases certainly lack the peculiar value which belongs to papers based upon collections of cases large enough to warrant broad generalizations, but they possess a value of a different kind, frequently not less positive.

Cerebro-spinal fever occurring in an epidemic form in districts where it was previously unknown, has not in all instances disappeared upon the subsidence of the epidemic. Occasionally sporadic cases continue to occur from year to year with such frequency and uniformity as to constitute the disease an endemic one in the true sense. This is, as I have recently pointed out elsewhere, the case with this disease in Philadelphia. The disease has become an abiding one with us, from sixty to ninety deaths having been ascribed to "cerebro-spinal meningitis," at the registration office of the board of health each year since 1873, the year in which the epidemic practically came to an end. These figures represent an extended, though numerically small prevalence of an affection having the characters of primary (idiopathic) cerebro-spinal meningitis and corresponding in all respects with the epidemic form. Neither at the bedside nor *post-mortem* can these cases be distinguished by any character whatever from those occurring during the destructive epidemics which have at long intervals overrun this country and continental Europe. The nature of the infecting principle of cerebro-spinal fever is involved in great obscurity—an obscurity greater than that of the cause of any of the other infectious diseases. To determine the identity or the non-identity of the causes of the sporadic and the epidemic cases, would be a long step in the direction of discovering the causes themselves. If they could be shown to be identical, the theory of a widely-distributed infecting principle (miasm) capable of a prolonged independent existence and under ordinary circumstances of feeble infecting power, would be alone tenable. In that case the development of special predisposing influences in individuals or communities would explain the sporadic or epidemic outbreak of the disease.

Incomprehensible as are the laws governing the spread of cerebro-spinal fever in epidemics, still more obscure and baffling are those which relate to the development of the sporadic cases. It is by the unremitting study of the latter, I believe, that we must attain a knowledge of the former. In the cases herewith narrated, the fact that the patients at different places had been exposed to like conditions of life, hot weather, sea-bathing, etc., sheds no light upon the causation of the attack. Thousands of persons at the same places, living the same life, failed to afford, so far as I can learn, another similar case of disease. The clinical history of these cases precludes the view of meningitis resulting from sunstroke or heat fever. The phenomena of such attacks were not present, the nervous symptoms were spinal rather than cerebral, and the evidences of an infectious rather than a simple inflammatory affection were ample. Moreover, the weather was far from excessively hot at the time of the development of each of the cases.

CASE I.—B. H., a bright, active lad of eight, whilst on a visit at the cottage of a relative at Spring Lake, N. J., was taken sick on Sunday evening, July 2, 1882, under the following circumstances: He had been at Spring Lake, a summer resort frequented by well-to-do people and never unduly crowded, for several weeks. There was not at that time any disease whatever prevailing in the settlement, which has been, since its origin, singularly free from sickness, and there was not then or in the neighborhood during the summer a single case in any way resembling that of B. H. A little

later a mild epidemic of whooping-cough made its appearance. B. H., had been constantly out in the air, but not unduly exposed to the sun; he had bathed in the surf every day. The day before he fell ill he had spent several hours in a boat fishing; the very day on which his illness began he had taken a moderately long walk, but had made no complaint of being tired, and had eaten a hearty supper of simple food. In the night he complained of being sick; on Monday morning he was feverish and vomited a small amount of undigested food. About noon he had a slight chill. I saw him July 3, towards evening. He then had slight fever, temperature 102°; pulse 120; and said his head hurt him. There were no other symptoms. Respiration not quickened; no undue redness of throat; no rash. I directed rest, regulated diet, milk and lime water, a little magnesia, and a small dose of sodium bromide at night. In the morning quinia sulphate gr. vj.

July 4.—The magnesia acted; patient passed a quiet night. Is feverish, complains of headache, but has no ringing in his ears; says that it hurts to swallow. Throat not reddened; tonsils not enlarged; no tenderness in region of angle of jaw. Tongue slightly furred. Temperature 104°; pulse 120. Chilliness, not amounting to a distinct chill, occurred about mid-day. The temperature was taken two hours later (104°). The area of splenic dulness is not increased.

Ordered sodium bromide grs. v q. s. h., and additional quinia, grs. vj, in the evening. And the same to-morrow morning.

5th.—1 P.M. Fever continues. Temperature 103°; pulse 112. Has vomited on two occasions a little mucus. About noon complained of chilliness, but it was slight and soon passed away. Swallowing still gives pain, and the head is held a little stiffly. To use the patient's own words, his neck is "Kind o' stiff." Nevertheless he can slowly turn his head from side to side and even bend his chin towards his breast. Pupils alike and react to light; neither contracted nor dilated; there is intolerance of bright light. There is tenderness over abdomen, but careful examination makes it evident that it is hyperæsthesia of the skin, not deep tenderness. The spleen is not enlarged. It is now evident that the illness is neither intermittent nor remittent fever. The quinia is discontinued. The sodium bromide is increased to grs. viij q. s. h., and with each one he is to have morphiæ sulph. gr. $\frac{1}{16}$.

6th.—A quiet night, but complains of pain and stiffness whenever awake. Bowels constipated. There has been occasionally slight vomiting without nausea, a little mucus or the milk, as the case may be, being thrown up. There is no longer any doubt about the diagnosis.

11 A.M.—Temperature 104.5°; pulse 120. 7 P.M. Temperature 105.2°; pulse 128. 10 P.M. Temperature 104.5°; pulse 140.

Pupils slightly contracted; patient disposed to sleep, but easily roused; mind clear; answers questions clearly, but constantly when awake complains of pain in back of neck. There is thirst and entire disinclination to take food.

7th.—Thirst less urgent; skin moist; lips slightly bluish. Heart sounds clear; no murmur. No disposition to vomit.

8 A.M. Temperature 103°; pulse 134; respiration 40. 5 P.M. Temperature 103.5°; pulse 120; respiration 35. 10 P.M. Temperature 101°; pulse 120; respiration 28.

Bowels, which have been constipated for several days, relieved by calomel in one-grain doses morning and evening. Brandy, a teaspoonful every fourth hour, and a four-grain suppository of quinia night and morning has added to the treatment, the morphia being at the same time reduced to gr. $\frac{1}{32}$ q. s. h.

8th.—Condition the same. 10 A.M. Temperature 102°; pulse 120; respiration 30. 7 P.M. Temperature 101.8°; pulse 120; respiration 36.

9th.—Decided improvement; had a good night; lips have lost lividity; head-pains have ceased; can move head from side to side and forward, and without pain, but still stiffly A plentiful eruption of acne has resulted from the bromide, which has been given less frequently for a day or so and is to-day stopped. P.M. Temperature 101°; pulse 120; respiration 36.

10th.—Improvement continues; strength better; asks to get out of bed. 10 A.M. Temperature 99.8°; pulse 100; respiration 32.

11th.—Complains of right shoulder, when upon examination I found a patch of herpes as large as a silver dollar. The morphia discontinued.

13th.—Fully convalescent.

16th.—To-day the patient was allowed to go to drive. From this time he rapidly gained strength, and continued well until his return to Philadelphia, in September. There were no sequels.

This case presented at the onset the characters of an ordinary intermittent fever and was so regarded by the friends of the patient and by myself until the third day. It was in fact an example of the so-called intermittent variety of cerebro-spinal fever. In this view, Drs. Hughes and J. M. Adler, gentlemen who saw this case with me, and who had abundant opportunities of seeing the disease in its epidemic form some years ago, unhesitatingly concurred.

Points of importance in the differential diagnosis from intermittent fever early in the attack, are the irregularity of the periodicity, the headache between the chills, and the failure of quinia to influence the fever even in doses of six grains twice a day for a child of eight. Later all doubts as to the nature of the sickness was settled by the development of spinal symptoms. I regard the outbreak of herpes upon the shoulder as of diagnostic moment.

CASE II.—The evening of Sept. 7, 1882, I saw, with Dr. Ellwood Wilson, Miss E. H., aged 18, at her home in this city. She was then about seven or eight days ill, and presented symptoms of the gravest character. I learned that she had spent part of the summer at Atlantic City, and had been whilst there in good health until the day before returning home, when she was observed to be somewhat listless and disinclined to exertion. She came to Philadelphia Aug. 29th, and although feeling out of sorts went, in accordance with previously ar-

ranged plans, with her mother, on Aug. 31st, to Elmira to visit friends. Upon her arrival there, she became at once seriously ill with headache of great intensity, nausea, stiffness of the neck, and nocturnal delirium of a distressing kind. Her mother was ordered to bring her home, where she arrived after a journey of great suffering, Sept. 5th. Her condition from this date was that of extreme illness, with great depression. On the 7th, the following notes were made at the bedside: A tendency to constipation has existed from the beginning of the sickness; the bowels have acted only once or twice, and that under the influence of medicines. The nausea which was distressing in the early days of the attack has ceased; there is no vomiting. The tongue is covered with a thick, whitish paste; there is slight tympany, but no abdominal tenderness, although it is carefully sought for, enteric fever being borne in mind. This suspicion is favored also by the fact that two or three days ago there was a slight attack of bleeding at the nose. There is painful stiffness of the neck and retraction of the head. The patient lies quietly, with her head burrowed back into the pillows, and objects to being disturbed. The headache has ceased; there is great intolerance to sounds, but moderate light does not disturb her. There is general hyperæsthesia of the skin. She cries out when even lightly touched. The pupils are of moderate width and react very sluggishly to light. They are alike; there is no squint. Occasionally slight general convulsive movements are observed. Pulse 128, full, but very compressible. Skin dusky and feet cool. There is no eruption. Mind perfectly clear. Urine highly albuminous, and up to this time not decreased in quantity.

8th.—Skin very dusky. Pulse full, soft, and very irregular, both as regards frequency and force. It fell, after the hypodermic injection of two fluid-drachms of brandy, from 140 to 120 beats per minute. Without this influence I found it varying 20 beats within ten minutes. Urine scanty and albuminous. It was not examined microscopically. Heart sounds clear and sharp; no murmur. Right lung deeply congested; respirations 40 per minute. The area of splenic dulness is not increased. The head is still retracted as yesterday; the hyperæsthesia intense over abdomen, chest, arms, and legs; the patient is dull (somnolent), but can be aroused. She dislikes being disturbed. Death took place in the afternoon. No examination of the body was permitted.

The following pulse and temperature observations were recorded:

Sept. 6th.—1 P.M. Pulse 100; temperature 102.9° 8 P.M. Pulse 104; temperature 101.5°.

7th.—9.30 A.M. Pulse 96; temperature 101.3°. 6 P.M. Temperature 105°. 8 P.M. Pulse 128; temperature 105.1°.

8th.—8 A.M. Temperature 105°. 9 A.M. Pulse 140; temperature 104°. 12 M. Temperature 103.5°.

The treatment from the time of the patient's return to Philadelphia consisted of artificial heat to surface of the body and limbs, free stimulation with brandy and champagne, small doses of morphia combined with ammonium bromide and sodium bromide, and calomel. What the treatment may have been previous to her starting upon the journey home, we could not learn.

The problem in diagnosis presented by this case related to the possibility of its being a case of enteric fever with spinal symptoms, first seen by Dr. Ellwood Wilson and myself, in a condition of collapse from some obscure intestinal lesion. It is true that in a small number of cases of enteric fever, and commonly in females, rigid contractions of the muscles of the trunk, extremities, and even of the neck, have been observed; cutaneous hyperæsthesia has also been reported in rare instances by competent observers. In enteric fever, as known to American practitioners, these are very uncommon symptoms.

Bearing in mind the possible recurrence of such symptoms in enteric fever, we were led to the closest scrutiny of the clinical features of the case. The abrupt onset of the sickness, which amounted to a formidable illness by the fourth day; the speedy failure of the vital forces, a condition approaching collapse developing by the end of a week; the brief illness; the early nausea, delirium, and frantic head-pains; the constipation, slight tympany, small spleen; tense, painful rigidity of the neck muscles; the exquisite and widespread hyperæsthesia; the intolerance of sounds, and the convulsions constitute a complexus of symptoms characteristic of cerebro-spinal fever, and widely at variance with enteric fever even in cases of anomalous kind.

It is to be regretted that an examination after death could not be made.

In general terms the treatment by the bromides, by opium or its derivations given early, and in full doses, calomel occasionally for its purgative effect, absolute rest and quietude, stimulus and artificial external warmth in the period of depression, and bland nutritious food in moderate quantities, promises both in theory and by experience the best results. In respect of the journey, the patient's mother spoke of her sufferings as *indescribable.* Nothing but the most urgent necessity can justify medical permission to a patient suffering from such an illness as this to take a long railroad journey to reach home.

MEDICAL PROGRESS.

INTERMITTENT FEVER AND ENDOCARDITIS.—LEYDEN divides his cases into four groups: first, cases where the endocarditis depends upon pyæmic and septic processes; second, cases where the endocarditis is associated with an irregular febrile process and erratic chills; the third and fourth groups consist of cases in which the causes of the fever correspond more or less closely with a typical intermittent fever, with paroxysms and states of apyrexia, not, however, always at perfectly regular intervals, though they may resemble a perfect quotidian or tertian type. These cases he again divides into two other groups, viz., intermittent fever without any previously evident heart lesions, and intermittent fever occurring in an individual with some compensated heart lesion. He believes that such cases are not invariably fatal.—*Centralb. f. d. Med. Wissen.*, November 4, 1882.

Tubercular Ulcer of Stomach.—Dr. Pisek, of Lemberg, records (*Deutsche Med. Zeit.*, No. 41) an instance of the above disease in the dead body of a man thirty-five years old. There were cheesy nodules in the right lung and peritoneum, with also some translucent tubercles in the latter. The mesenteric glands were enlarged and cheesily degenerated. The stomach was moderately large. On the pyloric region of the serosa, which was adherent to the liver, there were some semi-transparent tubercles. The ulcer existed on the mucous membrane near the pylorus on the posterior wall, was rather more than an inch long, and about an inch wide, of oval form; the edges were ragged, thin, undermined slightly, of gray color, and here and there infiltrated with yellowish granules the size of a pin's head; the ulceration extended as deep as the muscular coat. In the duodenum were two similar ulcers; nothing else in the rest of the intestines. No history of the patient's illness is given. Primary tuberculosis of the stomach is unknown. Tubercular disease of the stomach may, however, exist without affection of the rest of the alimentary tract. The diagnosis is not possible during life.—*Medical Times and Gazette*, November 11, 1882.

Treatment of Chancroids.—In relating his experience in the Lock Wards of the Edinburgh Royal Infirmary, Mr. A. G. Miller says that his treatment of chancroids has been modified very much, and latterly simplified, and also, he is sure, much improved, since the introduction of iodoform as a remedy. He used to cauterize these sores, especially when phagedænic, destroying them with caustic potash or chloride of zinc. Now he simply dusts them with iodoform powder and keeps them dry, and they invariably heal up in a few days.

Iodoform is especially useful in the female on account of its power of diffusing itself and penetrating into corners. Formerly, with the caustic treatment, he was never certain that he had destroyed all the sores, and knew that if one was left the chancroidal action would reproduce itself. Now he can be perfectly certain that if he puts on the iodoform freely the disease will be thoroughly checked. The action of iodoform on phagedænic sores is even more remarkable than on ordinary chancroids. His experience is that 24 hours, or at most 48, are quite sufficient to establish a healthy action in the sores. He uses the iodoform pure, the crystals being pounded to a fine dust, which is blown on to the parts affected by means of an instrument consisting of a wooden tube, widened out at the centre, where the powder is placed, and then blown out at the nozzle by pressure (with the thumb) on the India-rubber ball placed at the other extremity. When the labia are held aside by means of Dr. Henderson's forceps in the hands of an assistant, the surgeon can blow any quantity of the powder that may be necessary directly on the affected parts, and as these are always damp, a sufficient quantity of the iodoform adheres to destroy the septic action of the sores. If all the sores are not reached at first, a second or third application may be necessary. Generally there was sufficient dusted on to act on all the sores, even those that were out of sight.

Chancroids on a syphilitic person run an ordinary course, but are apt to be followed by condylomata.—*Edinburgh Medical Journal*, November, 1882.

Irrigation of the Bowel in Dysentery.—At the meeting of the Cincinnati Academy of Medicine held October 30th, Dr. Whittaker called attention to the obstinacy of chronic dysentery to treatment. Mr. Ward, of London, said that those cases that lasted longest, and finally got well, had least to do with therapeutics. The speaker had recently, at the Good Samaritan Hospital, a case of dysentery with fifteen to twenty discharges in the twenty-four hours. When the patient was first seen she had been in the hands of several physicians, and her case seemed hopeless. He gave her large doses of ipecac, thirty grains every four hours, in the beginning. The second dose controlled the discharges, but after the third or fourth powder they again became very bad. He then thought of trying irrigation of the bowel with a solution of nitrate of silver, after the method recommended by H. C. Wood, one and a half drachms to three points of water. This was carefully injected and the effect was very marked, the patient having but one stool in twenty-four hours. The collapse disappeared, but the next day the dysentery returned. He then gave two or three doses of opium to the patient to stimulate the brain, but it seemed to give her great discomfort. The second day the dysentery returned, when he again repeated the injection, but instead of nitrate of silver he used a solution of alum, one drachm to the pint of water, injecting as large a quantity as possible, which in this case was three pints. The discharge then ceased, and since then the patient has entirely recovered.

The irrigation method is nothing new in the treatment of dysentery. Sydenham treated his patients by drenching them with water, both by mouth and rectum. Aretaus spoke also of washing out the bowel, although neither of the old writers mentioned astringents.

Stephen McKenzie, of London, has recently advocated irrigation in this way, showing that no force was necessary, all that was needed being simply to pour in the water from a funnel and tube. It is a very great question if the action of the astringent has so much to do with the case as the flushing out of the detritus and the poisonous germ. The failure of the ipecac in this instance shook the speaker's faith in this remedy though he had seen chronic cases cured by ipecac in two days. He was under the impression that it would relieve almost any case except where there is an hepatic abscess. This was the second case where ipecac failed in the practice. The best results have usually come from the recent or acute cases.

In concluding the discussion, Dr. Whittaker said that the suggestion had been made that the distention of the bowel might as much have caused the beneficial result as the flushing out. As the bowels are frequently very much distended with gas where the disease is very severe, certainly the mechanical dilatation does not amount to anything. It is no longer tenable to exclude micro-organisms as a cause, because of chronicity of an affection, as the greater forms of life, like trichinæ, have been found in the tissues after twenty years. Dysentery is a disease which constipates the bowels, the scybala acting as irritants, hence it requires laxatives, not astringents, in its treatment. The truth is the internal use of astringents is contraindicated in every stage.

One of the gentlemen thought that the injection might be more efficacious in our latitude than in warmer climates. The speaker would remark that it was just in a warm climate, the East Indies, where the irrigation treatment was used with such success. Its failure in many cases may be due to the fact that the method was not carried out properly; the fluid must be allowed to run in so as to completely inundate the bowel. The large bowel in a full-grown male will hold six imperial pints.

Another member thought the disease might be due to exposure to cold. That theory may hold good in some cases, but the prevalence of the disease also in hot weather will not refer every case to this cause. Cold weather often puts a stop to epidemics of this disease. The contagiousness of the disease is also pretty

generally accepted. Formerly the explanation of a *locus minoris resistentiæ* was deemed sufficient to account for the cause of this, as of any disease after exposure, but the direct explanation has been afforded by the experiments of Pasteur with the attenuated virus of fowl cholera that a reduction of temperature will permit the growth of micro-organisms that would not grow without it.

As the disease is simply local and not constitutional, the secret of its treatment lies in topical measures, just as we treat any other local disease. It is necessary with the irrigation treatment that the quantity of fluid be large. Some agents are used with the water, not wholly without danger from being absorbed and setting up unpleasant constitutional results. Thus carbolic acid may prove dangerous from the absorption of the poison by the vast denuded surface of the intestine. So also unpleasant results may follow the use of nitrate of silver—argyrosis—so that a solution of common salt should be at hand to follow it. In the case reported the disease yielded so immediately to the alum irrigation that no matter what theory was propounded, the relation between cause and effect was clearly shown.—*Cincinnati Lancet and Clinic*, November 18, 1882.

Scarlatiniform Erythema in the Course of Acute Rheumatism.—At the meeting of the Société Médicale des Hôpitaux held October 13th, M. Hallopeau reported a case of acute rheumatism in which there occurred an intensely red, livid eruption on the entire body, accompanied by chilliness and exacerbation of the febrile movement and malaise, but with no anginose symptoms; the temperature of the skin to the touch was greatly increased. This lasted one week and then desquamation commenced in the form of white scales on the face and in large patches on the trunk and limbs. Three days later, pericarditis occurred, accompanied by intense dyspnœa and pulmonary congestion, and proved rapidly fatal.

At the autopsy there was found a marked thickening of the corneal layer of the epidermis and decided projection of the papillæ. The patient had had a similar attack accompanying an attack of rheumatism four years previously.—*Journ. de Méd. de Paris*, November 4, 1882.

Abortive Treatment of Facial Erysipelas.—Norregard (*Nordisk med. Arch.*, vol. xii., No. 27) has several times checked the progress of facial erysipelas by drawing a thick ring of collodion around the affected part, not over the whole surface, as by others. Dr. Christie mentions a similar case, in which the swollen skin bulged over the ring without being able to pass the barrier. The ring must be strong, especially on the bearded portion of the face.—*Arch. of Dermatol.*, October, 1882.

Albuminuria in Phthisis.—Dr. Cailleret, in a well-written thesis (*Paris Médical*) upon this subject, arrives at the following conclusions:

1. Albuminuria in the tuberculous is found in about one-sixteenth of the cases, according to the different statistics given.

2. Albuminuria is always a serious complication of phthisis; it may be transient or permanent.

3. Transient albuminuria in phthisis, as in all consumptive diseases, is a dyscrasic albuminuria, connected with a renal congestion; when permanent, it is dependent either on a tuberculous, epithelial, or interstitial nephritis, or upon an amyloid degeneration of the kidneys.

4. Albuminuria does not seem to influence the progress of pulmonary phthisis, or to hasten the evolution of tubercles.

5. The prognosis is always grave when there is a permanent albuminuria, for there can be no hope of cicatrization of the pulmonary lesions.

6. Milk diet is the one which has given the best results, and which ought to be applied, together with astringents.—*St. Louis Medical and Surgical Journal*, November, 1882.

The Temperature During Menstruation.—Dr. Kersch, of Prague, has drawn up a table of temperatures during menstruation, from which it appears that the normal temperature is not the same in all individuals; it varies between 99° and 97° Fahr. Moreover, during the first days of menstruation the variations in temperature are sometimes more, sometimes less (from 100.5° Fahr. highest, to 98.8° Fahr. lowest). From the second day onwards the temperature gradually sinks, so that on the day after the cessation of the flow it is again normal. It further appears that the process of ovulation sets in with a rise of temperature, which, in youthful individuals, may be as much as nearly 2° Fahr., and is at least 1.25° Fahr. According to Dr. Hennig, of Leipzig, the body-heat rises to about 99.5° Fahr., and again sinks to 98.5° Fahr. before the period, mounts again to 99.5° Fahr. on the day on which the flow begins, falls off shortly before the termination of the period to 97.5° Fahr., then rises again to 98.5° Fahr., at which it remains during the cessation, and immediately afterwards falls to 97.5° Fahr.—altogether three waxings and wanings: one before, one at the beginning, and one at the ending of the process. Hennig did an ovariotomy on a woman, aged forty-eight, whilst the menses were present, and noted the same evening a temperature of 101.3° Fahr. in the axilla, the pulse not being accelerated. The temperature next day was 101.5° Fahr., and on the third day after the operation 99.5° Fahr. This state of heat of the skin the author thought to be due to the menses. In another case of ovariotomy on a girl aged twenty, where menstruation came on seven days after the operation, the body-heat rose 2.5° Fahr.; the rise of temperature fluctuated during the menstrual period between 1.5° and 2.5° Fahr. (Hennig), and 1.25° to 2.0° Fahr. (Kersch).—*Medical Times and Gazette*, November 11, 1882.

The Pathology of Round Ulcers of the Stomach.—Quincke reports some experiments made by his pupil, Daetwyler, as to the pathology of gastric ulcers. These experiments showed that in dogs with gastric fistulæ, mechanical, thermal or chemical stimulation of the gastric mucous membrane produces very little effect, and that even when a circumscribed piece of tissue is removed by ligation and cauterization, it rapidly heals, leaving a circular depressed cicatrix; even when the loss of tissue is very deep, healing occurs in from fifteen to twenty days, when the dogs are in good health. When, however, they were rendered anæmic by previous bleeding, healing was very much delayed, and the constitutional effects were much more marked. So, also, while ordinarily in the human stomach loss of tissue can be rapidly repaired, in anæmic or chlorotic subjects, in whom the processes of nutrition are inactive, they may become chronic and degenerate into ordinary chronic gastric ulcers.—*Gaz. Méd. de Paris*, November 4, 1882.

The Etiological Relations of the Bacillus Tuberculosis to Tuberculosis.—Dr. H. F. Formad, Lecturer on Experimental Pathology in the University of Pennsylvania, has been conducting an elaborate series of researches on this subject, from which he draws the following deductions.

1. The predisposition to tuberculosis in some men and animals, the so-called scrofulous habit, lies in the

anatomy of the connective tissue of the individual, the peculiarity being a narrowness of the lymph-spaces, and their partial obliteration by cellular elements.

2. Only beings with such anomalous structure of connective tissue can have primary tuberculosis, and such animals invariably do become tuberculous from any injury resulting in inflammation, or from repeated injuries.

3. Scrofulous beings can have no other than a tuberculous inflammation, although it may remain local and harmless.

4. Non-scrofulous men or animals may acquire the predisposition to tuberculosis through malnutrition and confinement, the latter bringing on the above-mentioned anatomical peculiarities in the connective tissue.

5. No external etiological influences are necessary to cause tubercular disease other than those which ordinarily produce inflammation, and even scrofulous beings will not become tuberculous unless local inflammation is set up. No inflammation, no tuberculosis.

6. Non-scrofulous animals, so far as can be established now, may acquire tubercular disease through injuries of serous membranes, viz., peritoneum, pleura, etc., and even here without any special virus whatsoever. Clinical observations on the post-mortem table show similar conditions and prove the same in man. (Dr. Formad also claims that Koch's own experiments are also in favor of this proposition; but that he has overlooked this.)

7. The bacilli, which it is the merit of Koch to have first proved to infest tissues affected by tubercular disease, are not necessary for its causation, even if a special organism exist and be really possessed of such property. The presence of bacilli (so far as our present research goes) is secondary, and appears to *condition* the complete destruction of the tissue already diseased and infested by them, and this destruction is in direct proportion to the quantity of the organisms, which thus regulated the prognosis. The tubercular tissue seems to serve merely as a nidus for the growth of the bacillus.

8. From the results of microscopic examination, from numerous observations upon the post-mortem table, and on clinical grounds, he has come to the conclusion that phthisis is not a specific infectious disease, but that the individuals suffering from tubercular disease are specific themselves originally, and form a special species of mankind, the "scrofulous."

9. Scrofulosis is a condition which may arise from malnutrition and seclusion in any being, and thus may be produced artificially. It always depends upon the demonstrated anatomical changes in the connective tissue.

10. An analysis of Koch's experiments shows that he has not proved the parasitic nature of phthisis, or that there exists a special Bacillus tuberculosis; so that the infectiousness of tubercular disease is still *sub judice*.—*Philadelphia Medical Times*, November 18, 1882.

CYSTIC TUMOR OF NECK; INCISION; SUPPURATION; SUDDEN HEMORRHAGE: DEATH.—The following case occurred under the care of MR. SAVORY, in St. Bartholomew's Hospital: A. B., a cabman, aged fifty years, was admitted into Abernethy Ward, St. Bartholomew's Hospital, March, 1870, under Mr. Savory's care. He presented a soft swelling on the right side of the neck, coming from below, and partially overlapping the sterno-mastoid muscle. The presence of fluid being suspected, a small incision was made into the swelling, and some two or three ounces of clear cystic fluid were evacuated. During the next three days a slight discharge continued, which then became purulent; this continued during the next ten days. At midday the ward-sister was called to the patient, who was sitting up in bed, with a jet of blood spurting out through the sinus. The Surgical Register, who happened to be in an adjoining ward, was immediately summoned, and arrested the hemorrhage by digital pressure on the carotid. Mr. Savory upon seeing the patient half an hour later, sent him at once to the theatre, Mr. Symonds still continuing pressure on the wound. After anæsthetizing, the finger was removed, when the hemorrhage at once recommenced. Mr. Savory laid the sac freely open, and turned out a quantity of blood-clot. After careful search the bleeding orifice could not be found; the pulsation of the carotid was felt in the deeper parts of the wound. The artery was therefore cut down upon by slightly extending the incision, and tied with a silk ligature. The patient, however, who was much exhausted before the operation commenced, never recovered consciousness. He died comatose next day.

At the autopsy an opening was found in the external carotid artery about half an inch above its bifurcation.—*Medical Times and Gazette*, November 11, 1882.

PEPTONURIA.—DR. RUDOLF JACKSCH shows that peptonuria is rarely met with in infectious diseases, or in pernicious anæmia, or leukæmia. The absence of peptonuria in the latter disease is remarkable, since the blood in such cases is usually found to be rich in peptone. Peptonuria generally occurs in the stage of resolution of pneumonia, and lasts ordinarily for two days after the process is completed; so also in cases of pleuritic exudation, peptone is generally found in the urine, and usually in increased amount when resorption commences. Peptonuria can also be detected in meningitis, in phosphorus poisoning, and in cases of scorbutus.—*Wiener Med. Presse*, October 22, 1882.

SYPHILITIC AFFECTIONS OF THE EYELIDS.—DR. THEODORE WIETHE contributes three cases of lid-syphilis under as many forms, viz.: 1. Initial sclerosis of the lower lid. 2. Ulcerated papule of the upper lid. 3. Gumma of the lower lid. He introduces the statistics of Zeissl, who, among 40,000 cases of syphilis, saw only eight of affections of the lid, and remarks that the oculist meets with but one undoubted case of syphilis of the lid in 10,000 eye patients. A lengthy description of each case is given, with references by comparison to the cases of Arlt, Hirschler, Desmarres, and Galezowski. Treatment consisted of iodide of potash, inunctions of mercury and iodoform locally: recovery followed in each case. It is worthy of note here, that the microscopical examination of a section of the gumma taken from its groundwork gave swollen fibrillæ of connective tissue.—*Arch. of Dermatol.*, Oct. 1882.

THE ELASTIC BANDAGE IN THE TREATMENT OF VARIOUS SURGICAL DISEASES.—SÉE (*Bull. de la Soc. de Chir. de Paris*) speaks highly of the elastic band in the treatment of the following diseases: 1. Œdema of the limbs due to cardiac, hepatic, or venous disease, or to cachexiæ. 2. As an adjuvant to massage in the treatment of sero-plastic effusions remaining after diffuse phlegmon. 3. Interstitial effusions of blood due to contusions, etc. 4. Chronic serous arthritis after acute joint disease. 5. Circumscribed or diffuse inflammation in all stages of its development. The elastic support here replaces the weakening poultice, and is, besides, superior to the latter through its influence over the blood-flow. 6. Ecthyma of the limbs, and ulcers (atonic, callous, varicose). 7. Recent sutured wounds. The bandage is here applied over a Lister's dressing. Certain general precautions are to be observed, such as extremely slight pressure, exact overlapping of each turn, and the elastic band to be changed every two or three days and washed in a solution of carbolic acid.

The bandage acts by its constant equable pressure, it also retains the cutaneous secretion (thus acting more or less as a tepid compress or poultice), and by preventing the entrance of spores, etc., effectually aids the antiseptic dressing.—*Edinburgh Medical Journal*, November, 1882.

Treatment of Epilepsy.—Dr. Saundby read a paper before the Midland Medical Society, on October 25th, on the treatment of epilepsy, in which the following points were insisted on.

1. The value of combining the bromides of potassium, sodium, and ammonium, as recommended by Professor Brown-Séquard; 2. The advantage of adding tincture of digitalis, and sometimes theine, to the mixture, to counteract the depressing influence of the bromides; 3. The utility of zinc as an adjuvant in the treatment; 4. The successful use of borax in some cases of obstinate epilepsy, of which two illustrative cases were given; 5. The value of theine or caffeine and nitro-glycerine in the treatment of epileptic vertigo.—*British Medical Journal*, November 11, 1882.

Lung with Impacted Foreign Body.—Dr. Norman Moore, at the meeting of the London Pathological Society held November 7th, showed the right lung of a girl aged twelve years, who died of typhoid fever. The lung was partially collapsed, and in its lowest lobe were several reddish patches. In one of these, near the pleural surface, was fixed a spicule of bone, one-third of an inch long. The spicule, which looked like the neural spine of a fish vertebra, had one end in a minute bronchus, the wall of which it had penetrated. Four years ago the child was suddenly seized with pleurisy. She was tapped in St. Bartholomew's Hospital, pus was let out, and, as the wound continued to discharge, a drainage-tube was put in. The child attended with this as an out-patient, and at length the wound was closed. The scar was distinct, and beneath it the lung was firmly adherent to the chest-wall. The spicule of bone, passing deep into the lung, probably set up a pneumonia, which was followed by the empyema four years ago. The empyema was concluded, but the bone remained fixed in the lung—a very exceptional circumstance. The typhoid fever of which the girl died was remarkable in the large extent of intestine affected, and in the fact that the middle part of the vermiform appendix was externally tumid, and internally ulcerated all round. Perforation of the vermiform appendix had occasionally been a cause of death in typhoid fever, and had been ascribed to a condition preceding the fever. In this case, and in another post-mortem which he had lately made, the ulceration of the vermiform appendix was clearly one of the results of the typhoid fever. A further point of interest was that in the middle of the epiglottis there was a small ulcer.—*Medical Times and Gazette*, Nov. 11, 1882.

Chronic Interstitial Hepatitis.—From numerous experiments Dr. Maffuci (*Lyon Médicale*, September 3, 1882, from *Il Movimento, Giron. dei Scien. Med.*, 1882, No. 2) has formulated the following statements:

1. Hepatic cirrhosis is always situated in the tissues surrounding the portal vein.

2. The periphlebitis is produced by the presence of chemicals or virulent poisons in the blood circulating through the vein.

3. The inflammatory process is similar to that which is observed in all the other organs; it is characterized by hyperæmia with migration of leucocytes, and by the organization of the exudations.

4. The periphlebitis is perfectly distinct from the interstitial inflammation of the liver provoked by the presence of biliary calculi.

5. The serious affection of the nutrition of the hepatic arteries determines the necrobiosis of the liver.

6. The interstitial alterations of the liver provoked by the arterial lesions are very different from those caused by the periphlebitis.—*Glasgow Medical Journal*, November, 1882.

Acetal as a Hypnotic.—Dr. von Mering read a paper, at the recent meeting of German philosophers at Eisenach, on the value of acetal as a hypnotic (*Berliner klin. Woch.*, October 23). Acetal is a volatile fluid of ethereal odor, sparingly soluble in water, though some of its derivatives are very soluble in alcohol and water. Experiments were made on frogs, rabbits, dogs, and cats. Acetal first acts on the cerebrum, causing gradual loss of consciousness; it then paralyzes the functions of the spinal cord and medulla oblongata, stopping the breathing before arresting the action of the heart. The drug has been administered subcutaneously, by the mouth, and by intravenous injection. Asphyxia, or rather apnœa, was the cause of death when that result ensued. It is remarkable, says the author, that such bodies as alcohol, ether, paraldehyde, acetal, and several other bodies not containing chlorine, act primarily and more powerfully on the respiratory centre; whilst after the administration of such substances as chloroform, chloral hydrate, and bichloride of methylene, the circulation and respiration are pretty equally affected. Eight experiments only with acetal have been made on men; six times there was a notable effect, both in the relief of pain and the procuring of sleep. Further details are promised.—*Medical Times and Gazette*, Nov. 11, 1882.

A Theory as to the Unity of Origin of Rheumarthritis, Carditis, and Chorea.—Mr. William Stewart gives the following as a *résumé* of his theory:

1. Follicular tonsillitis, by the process of mild inflammation, originates the discharge of altered white blood-corpuscles through the follicular openings on the tonsils. 2. These, or others in the tonsils not extruded, are re-absorbed into the blood by the lymphatic vessels through the glands at the angle of the jaw. 3. By the initial inflammation, the white blood-corpuscles are deprived, to a certain extent, of their normal physiological qualities; and to the same extent as they have been devitalized they acquire pathological properties, by virtue of which they have an intensified tendency to adhere to the inner walls of the capillaries and to one another, and also to pass through the capillary walls into the connective tissues, and there form deposits. 4. They in this way become pathogenetic cells, and produce disordered nutrition and perverted functions in those organs in which they are interrupted or extruded, and thus establish the phenomena of disease. 5. These devitalized cells are revitalizable, and therefore the diseases which they produce as a rule terminate in recovery. 6. This theory explains the altered blood-condition observed in these affections, which is established by repeated absorption of cells or by the individual cells communicating to other cells they meet in the blood the same impress which they have already received. 7. It accords with the apparent origin of rheumarthritis from damp and cold, and of chorea from fright, by according to them the power only of acting as exciting causes. 8. It does away with the necessity of a causal connection between any members of the group; and, finally, that it explains, in a rational and probable manner, the known clinical connection between, and the morbid anatomical conditions existing in, the various diseases of the group.—*British Medical Journal*, November 11, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, DECEMBER 2, 1882.

DEATHS FROM CHLOROFORM.

OUR esteemed contemporary, the *Virginia Medical Monthly*, in its issue for last month, contains the record of a case of death from the administration of chloroform as an anæsthetic. The report is made by Dr. Hunter McGuire, and is characterized by the fidelity to truth, which any one, who has any knowledge of his good qualities, must expect from this distinguished surgeon. The account is very circumstantial. Whilst Dr. McGuire sat with his finger on the pulse, the inhalation proceeding, "the pupils of both eyes slowly dilated to two or three times their natural size." Dr. McGuire, probably somewhat startled, "spoke to her, and she answered intelligently," but as she spoke "the pulse suddenly stopped; it did not flutter and gradually fail, but abruptly ceased . . respiration continued for some seconds after the pulse ceased beating at the wrist." Dr. McGuire attributes the sudden cessation of the circulation to "cardiac paralysis." It is not often that the attendant phenomena are so coolly and dispassionately observed as they were in this instance; hence the case has peculiar value as an illustration of one mode of dying from chloroform. Preliminary examination of the heart and lungs disclosed no signs of disease of these organs. "About one drachm of Squibb's chloroform" was first poured on the towel, and the inhalation had proceeded about two minutes when the heart was paralyzed.

Dr. McGuire has operated under chloroform narcosis and has administered this anæsthetic, in all some thirteen or fourteen thousand times, without accident, except in one case, where the fatal result may have been fairly attributed to other causes. We may, therefore, assume that all the usual conditions had been faithfully observed, and that the inhalation was conducted with strict attention to the necessary details. Yet within five minutes after commencing the inhalation the patient was dead.

What is the lesson of such a death from chloroform? In the absence of any apparent cause what is the explanation of this untoward result? There are two elements of prime importance. First, the mode of inhalation. We have more than once in these columns insisted on the danger incurred by the administration of chloroform in the mode pursued in this instance. We are perfectly well aware that no method of administering anæsthetic vapors is more common. A towel converted into a cone having an opening at the apex is the usual inhaler employed. The chloroform poured into the interior of the cone is rapidly vaporized. In the case of Dr. McGuire, the cone was not at once applied to the mouth and nose. In the language of the report it is stated, "To avoid the danger of giving the vapor in too concentrated a form, the napkin was first held several inches from the face and gradually brought closer to her mouth and nose."

The least consideration of the vapor-density of chloroform ought to satisfy any one that, given in this way, the air is almost entirely displaced by chloroform, and hence, notwithstanding that the towel-cone is held some distance from the mouth and nose, for the most part chloroform-vapor must necessarily be inhaled for much of the time. As the proportion of chloroform-vapor to air should be not more than three or four per cent. to insure the safety of the inhalation, it is obvious that this canon is violated when the manner of inhalation is practised as in Dr. McGuire's fatal case.

In our comments on another recent case, that of Dr. Kinloch, of Charleston, we insisted on the observance of that maxim which, in the case of chloroform-vapor, requires a proper admixture of air. In the usual methods now employed for the inhalation of this agent, too little attention is paid to this point. Chloroform is either poured on to the interior of a cone made from a towel, or is dropped on a cloth laid over the patient's mouth and nose. In either case the patient first inhales almost pure chloroform-vapor, and hence the cardiac motor ganglia are quickly acted on, and in this way may be explained the sudden access of cardiac paralysis.

The second element which may serve to explain the unfortunate result in Dr. McGuire's case, is idiosyncrasy. There may have been some original susceptibility to the action of the anæsthetic. The absence of any cardiac and pulmonary lesion, proves that the fatal result must be attributed either to the sudden overwhelming of the heart by undi-

luted chloroform-vapor, or the existence of a peculiar susceptibility which renders any considerable quantity of the anæsthetic, itself, dangerous.

The final consideration is, what anæsthetic is least dangerous under ordinary circumstances? In the face of so many untoward results from chloroform, are we not bound by every consideration, professional or moral, to use ether, which is unquestionably a less dangerous if not as agreeable anæsthetic? This is the more true, since even in the hands of such able and judicious surgeons as Dr. McGuire and Dr. Kinloch, accidents will occur from the use of so unsafe an agent as chloroform.

As we close the remarks on Dr. McGuire's case, the *Nashville Journal of Medicine and Surgery*, for November, comes to us, having for its first article a case of "Fatal Chloroform Narcosis Administered in the Operation of Teeth Extraction." The anæsthetic was administered by Dr. J. F. Byrn, of Murfreesboro, Tenn., and the extraction of teeth was done by Dr. Hartman, the dentist. Mrs. Smith, the subject, was aged 30, and was the mother of five children. She had taken chloroform several times before, for the same purpose, without any unpleasant symptoms. Dr. Byrn and Dr. Hartman tried to dissuade her from her purpose, and represented the danger of the proceeding—the especial danger—since the extraction of teeth under chloroform had been the cause of death in numerous cases. She, however, persisted in her purpose, and took her place in "the operating chair"—a nearly upright position. Dr. Byrn placed a quantity, estimated at two drachms, "on a folded towel," and the inhalation proceeded, Mrs. Smith passing quickly into unconsciousness. Two teeth were extracted, and as the operator was about to seize the third it was observed that "her respiration was becoming embarrassed, and her eyes were open, fixed, and staring." The usual steps were taken to avert the fatal result, but without avail.

There are several very important considerations involved in this case, and as medical journalists it is our duty to utilize them to point an obvious moral. Before giving the anæsthetic the poor woman was warned of the danger, but was this sufficient? Recognizing as they did the enormous danger of the procedure, ought not the physicians to have declined to administer this anæsthetic? A resolute adherence to a right position would most probably have saved a human life.

The mode of administering the chloroform, on a folded towel, so held as not to permit free dilution with air, is that which we have shown to be especially dangerous, and in this case we have an additional illustration of the truth of this assertion. Mrs. Smith, although calling for more chloroform, passed promptly into the anæsthetic state, because she inhaled nearly pure chloroform vapor. She passed the danger point due to the first impression of the chloroform vapor on the cardiac ganglia. To what then must the death be attributed? It has been abundantly demonstrated, that operations in the domain of the fifth nerve, under chloroform narcosis, are peculiarly dangerous. The reason is obvious. The nucleus of the fifth and the nucleus of the pneumogastric lie in close juxtaposition, and intimate reflex relations, if not direct commissural connections, subsist between them. The impression made on the end organs of the fifth, in tooth extraction, exert a powerful stimulant effect on the inhibitive function of the pneumogastric. Such is the mechanism. It is readily illustrated on a rabbit. If placed in a Czermak's holder, and a needle having a paper flag attached to its outer extremity, is thrust through the walls of the chest into the muscular substance of the rabbit's heart, the movements of the paper flag will indicate the heart's movements. Chloroform vapor must be very cautiously administered, and when sensibility is induced, some irritation, as drawing a tooth, must be suddenly applied to the jaw; the heart is immediately stopped.

The danger of tooth-drawing under chloroform anæsthesia being so pronounced, and so readily explained, we hold that no physician is justified in encountering such risks. Any one happening to such a terrible accident, in the face of the abundant warnings, must ever afterward experience keen regrets.

"Those wounds heal ill that men do give themselves,"

says Shakespeare.

The usual means of restoration, we remarked above, were employed, but one of these expedients, we hold, is not justifiable. We refer to the hypodermatic injection of brandy. We observe in the accounts of such accidents an increasing use of the subcutaneous injection of some form of alcoholic stimulant. As chloroform and ether are derivatives of alcohol, and belong to the same group—the cerebral sedatives—it is certain that they closely correspond in their effects on the intra-cranial organs. To throw whiskey or brandy under the skin, in cases of anæsthetic depression due to chloroform or ether, is adding fuel to the flame. The best mode of treating the dangerous symptoms arising during anæsthesia is too important a topic to be considered here. We may at some future time set forth our views in a special article.

HEALING BY FAITH.

An age of disbelief is diversified by a return to miracles. The evangelists, Barnes of Kentucky, and Simpson of New York, are now demonstrating that miraculous interposition, supposed to have

ceased with the era of primitive Christianity, has again returned to the earth. If only faith be sufficient, all maladies are cured by prayer and the anointing with oil, say these teachers. Their words are proved by their works. In the same way, many a decrepit and sick pilgrim, repairing to the sacred spring of Our Lady of Lourdes, is miraculously healed. Those scoffing unbelievers who laugh over these evidences of healing, have little conception of the remarkable results which may be achieved by an unquestioning faith. It is, however, a necessary preliminary, that those who seek to be cured shall have an absolute conviction that the means are adequate to the end. If this faith be wanting, the effort at cure, no matter how zealously made, will fail. When we come to examine the list of cases thus miraculously healed, we find that they consist, for the most part, of nervous and hysterical maladies. In the *New York Tribune*, of November 19, there is given a list of those cured by Mr. Simpson. They are examples of aphonia, of pains, of paralysis, of useless joints, etc., which all practical physicians know to be of neurotic or hysterical origin, and curable by a strong mental impression of some kind. How desirable soever it may be to have the power to produce miracles revived on the earth, it is quite clear that these evangelists have done no more than is daily accomplished by those peripatetic medical charlatans who cure by "laying on of hands." They have not accomplished more difficult feats than that Massachusetts doctor who cures by prayer without fees, but who has built up a great establishment as a testimony to his powers. To him not long since a lady with heart-disease (valvular) repaired, full of faith that his intercession in her behalf must succeed. On learning the nature of her case, he gravely shook his head, and said, "in his experience, the Lord rarely interfered in such cases."

Sir Humphry Davy, when a young man, had an experience which serves to illustrate the nature of healing by faith. Davy was employed by Dr. Beddoes, who had an extravagant theory of the curative power of oxygen, to administer the gas to certain patients. Amongst those who came to be treated was a paralytic. Before beginning the inhalation, Davy placed a thermometer under the patient's tongue, to record his temperature. The man was much impressed with this, and declared with great enthusiasm that he was already much relieved. Seeing the extraordinary influence of the man's imagination, Davy did nothing more than gravely place the thermometer under his tongue, from day to day, and in a short time he reported cured.

Those of our readers interested in this question—and what physician is not?—will find an excellent summary of our existing knowledge in Tuke's work on the *Influence of the Mind over the Body*. Here are recorded, amongst other curious examples of mental influence, the remarkable miracles performed during the first part of this century by the priest-Prince Hohenlohe, which equal the deeds done by our contemporaries, Barnes and Simpson. Doubtless, in all ages, especially in troubled states of society, and during times of pronounced unbelief, there have risen up teachers pervaded by such profound convictions as to impress all about them with a belief in their possessing supernatural powers in the cure of disease. In making these statements we wish merely to express our theory that these evangelists accomplish their results through agencies well known to the medical profession, and, in common with most believers, we hold that the age of genuine miracles has passed. Our comments on the work of contemporary evangelists are intended merely to impress our readers with the physiological aspect of these miraculous cures, and we are, therefore, not in sympathy with those who distrust the results achieved by the influence of faith and prayer. Indeed, from our point of view, we hold that Barnes and Simpson are, in a limited sense, engaged in a work of utility quite irrespective of theological considerations, since they are unquestionably curing a certain class of cases through a strong mental influence. At the same time, there is always danger in such cases that the enthusiasm aroused by supposed miracles will degenerate into delirium.

There is yet another medical question connected with these periodical outbreaks of religious fervor. We have read the history of moral epidemics to little purpose if we have not recognized the injury done to the nervous system of those subjected to the enormous strain of an all-pervading religious enthusiasm. The attacks of chorea, of epilepsy, of mania, which follow in the wake of extreme religious excitement are known to all practical physicians. It becomes the duty, therefore, of the medical profession to restrain, as far as may be in their power, the injurious influences of religious excitement, whilst refraining from interference in all healthy spiritual development.

AN IMPORTANT CHANGE IN THE STRENGTH OF OPIUM AND ITS PREPARATIONS IN THE NEW PHARMACOPŒIA.

IN the number of the *Ephemeris of Materia Medica* for November, Dr. Squibb calls attention to the change in the strength of medicinal opium and its preparations effected by the Pharmacopœia of 1880. The notice is timely, for no other drug, perhaps, is so constantly used, and no other one certainly vies with it in importance as to definite, constant, and known strength. To state it briefly, *the strength of all these preparations is increased about 50 per cent.*

The Convention directed that "in liquid opium preparations, excepting paregoric, the strength of 10 per cent. shall be adopted if deemed advisable." This has been done, and on page 454, in a "Table exhibiting differences of strength," the consequent increase of 10 per cent. is stated. But so misleading is this statement that as accomplished a pharmaceutist as Dr. Squibb himself, while revising the proof-sheets of the Pharmacopœia, overlooked the fact that the *strength* of opium itself, as well as the *percentage* contained in its preparations, has been increased and thus adds about 40 per cent. more to the strength of the opium preparations. As Dr. Squibb shows, the change is a judicious one, and in the direction of accuracy, but we are surprised that prominent notice of the fact has not been given in the Pharmacopœia.

Surely not only this should have been done, but a much greater uniformity in the preparations of opium should have been insisted on. The Pharmacopœia prescribes that in making them an opium assaying "not less than 12 nor more than 16 per cent." shall be used—a difference of 33 per cent! This will give with a 12 per cent. powder 5.44 grains of morphia to the fluidounce, and with a 16 per cent. powder 7.25 grains. Why should not other chemists be able to fix a *definite* standard, as Dr. Squibb has done, and make the liquid preparations of opium contain 6 grains of morphia, the alkaloid (that is, 7.5 grains of sulphate of morphia), to the fluidounce? Or, rather, why should not the Pharmacopœia itself do this?

Dr. Squibb suggests, and it should certainly be followed, that hereafter, in prescribing these liquid preparations, the figures "1870" or "1880" be added to show which preparation is desired. It is of the utmost importance that both the profession and the public understand the change. If not, we must face the possibility of accident through entire ignorance, but for which the courts will properly hold us responsible. We hope the lay press also will assist in diffusing a knowledge of the change.

THE JOHNS HOPKINS UNIVERSITY.

OUR Baltimore correspondent calls attention in another column to the completion of the new biological laboratory, and to a most important question in connection with this splendid University endowment. Shall the Medical School enter the lists to compete with the unendowed schools all over the land in turning out doctors of ordinary education, or shall it devote itself, as it alone has the means of doing, to the higher medical teaching only, and give us thoroughly educated scientific men, students who are competent to engage in original research, and men fitted to fill professorial chairs?

Were the answer of local consequence alone we should not allude to it, but this is a University which is peculiarly of national importance, and is fortunately hampered neither by statute nor tradition. We have already ten medical schools where one would do, as we showed some weeks ago. Another of the same class would not only be a superfluity—it would be a calamity.

Great Britian has just started an "Association for the Advancement of Medicine by Research." Johns Hopkins University can perform precisely the functions of such an association in this country, and a great deal more. Its endowment, its hospital, its laboratories, its equipment, above all its able and distinguished President and Faculty give assurance of what its students ought to be, and what we hope they will be—competent, thorough, laborious, and distinguished.

Those who are charged with the execution of this munificent trust now have it within their power to create a school in which can be had such an education as is now unattainable on this continent, and from the lack of sufficient endowment is beyond the scope of any of our existing medical schools. We trust that this grand opportunity, which appears to have been part of the design of the founder, will be embraced by his trustees. The John Hopkins University will then supplement the existing medical schools and will have the whole country for its field of benefaction.

DR. AUSTIN FLINT, of New York, delivered in this city last Saturday evening, the first of his course of three lectures before the Philadelphia County Medical Society, on the physical exploration of the lungs by auscultation and percussion, before a medical audience such as has not been seen in this city for many years. Although the subject was one about which there was not an atmosphere of novelty, yet it was so freshly and suggestively treated by the distinguished clinician, that all felt that the evening had been of profit as well as pleasure.

The lectures will appear in these columns at an early day.

GOVERNOR-ELECT PATTISON will have one officer to appoint in whom the medical profession of this city have a deep interest—the Health Officer of Philadelphia, and we hope that Mr. Pattison will rise above party traditions and follow the indications of a true civil service reform.

Mr. John E. Addicks, the present incumbent, has been Health Officer for a number of years, and has the familiarity with his duties which only long experience can give. He is an efficient officer, courteous, and yet bold and prompt. Not a word of suspicion have we ever heard against his entire integrity. Although he is a Republican, we hope

that Mr. Pattison's civil service reform views will prompt him to retain such a capable officer. By so doing he will gratify many Republicans who voted for him, and all of both parties who are sincere reformers.

We notice with satisfaction that the Court of Special Sessions in New York has fined a number of dealers in sums of from fifteen to one hundred dollars for adulterating the milk they were selling.

Milk is so important an article of food, not only because it enters so largely into the food of adults, and especially of infants, but because disease, as is now well known, is so readily and so certainly carried by milk, that its purity should be most carefully looked to. It is more than a mere question of money, it is often one of life and death. Would that other cities had as stringent laws and as efficient sanitary inspectors as New York.

REVIEWS.

CLINICAL SURGERY. EXTRACTS FROM THE REPORTS OF SURGICAL PRACTICE BETWEEN THE YEARS 1860–1876. By DR. M. BILLROTH, Professor of Surgery in Vienna. Translated and edited with annotations by C. T. Dent, F.R.C.S., etc. With plates. 8vo. pp. xx. 518. London: The New Sydenham Society, 1881.

THIS volume is not to be mistaken for a systematic treatise on surgery; it is a collation of reports of clinical experiences of Dr. Billroth, during a period of sixteen years. But it is not a mere collation of these reports. They have been edited and rearranged so as to group cases of a like kind, and notes have been added by the translator, so that the reader is presented with not only what Billroth thought and did in years gone by, but also his belief and practice at the present day.

The translator has thus enhanced the value of these reports above that which they possessed in the original. He has also judiciously suppressed the mass of statistics with which the latter were burdened, citing Billroth's own remark: "Statistics, like women, are a mirror of purest virtue and truth, or public prostitutes to be put to any use one may wish." He has also added a useful index and reproduced ten extremely interesting and well-executed full-page plates, illustrating the context.

It would be impossible, within the limits we can spare, to give any idea of the wealth of experience this book lays before the reader. It is only possible to commend it as a mine from which the practical surgeon can dig out something of value upon almost any conceivable subject in surgery.

FISTULA, HEMORRHOIDS, PAINFUL ULCER, STRICTURE, PROLAPSUS, AND OTHER DISEASES OF THE RECTUM: THEIR DIAGNOSIS AND TREATMENT. By WILLIAM ALLINGHAM, M.D., F.R.C.S., etc. Fourth revised and enlarged edition. With illustrations. Large 8vo. pp. viii. 167. Philadelphia: P. Blakiston, Son & Co., 1882.

AFTER one has gazed at each member of the long title of this well-known work, is it a relief or a disappointment to discover that the "other" diseases of the rectum hinted at are but impaction of feces, cancer, and neuralgia? Let each reader decide for himself; we at least find it a relief. For, setting aside for the moment the value of the author's opinions, and regarding only his literary style, we are thankful that his ambition rose no higher, nor diffused itself over any more widespread field. And, if we fix our mind rather, as we ought, upon the value alluded to of the author's opinions, we can still feel no regret that it is possible to get at them all without stumbling over any more rough and stony literary obstacles than are here scattered about.

The author needs no commendation, nor need he fear any fair criticism of his matter, for he speaks from a long and well-digested experience. He is a recognized authority in regard to the subject of this book. So we do not address ourselves to this feature of it, but we do criticise its style, not in any captious spirit, but because we think too little attention is paid, now-a-days, to this part of authorship among medical writers. It is not enough that an author shall serve his readers with good fare, he must e'en serve it handsomely, or he shall not escape our complaint.

SOCIETY PROCEEDINGS.

SUMTER COUNTY (ALA.) MEDICAL SOCIETY.

Stated Meeting, October, 1882.

J. N. GILMORE, M.D., PRESIDENT, IN THE CHAIR.

(*Specially reported for* THE MEDICAL NEWS.)

DR. E. H. SHOLL, of Gainesville (appointed at a previous meeting for this purpose), introduced as a subject for consideration,

CINCHONIDIA.

After a very large practical experience in the use o cinchonidia, he was prepared to say that it fully met his expectations as to its *antiperiodic* and *antipyretic* effects; that he relied on it in the gravest cases with as much dependence as on quinia, and in the same doses. He detailed his experience with it in a very severe case of double pneumonia in a negro man, where its prompt and decided antipyretic effect, in doses of twenty-five grains each morning, was marked, and contributed to the favorable termination; reducing the temperature in three days from 105° to 99°. From its effects in this case he was led to believe it possessed also, in a high degree, the antipyretic property of quinia.

He had also used it hypodermically, in solution by boiling water, and by means of tartaric acid, as recommended by Dr. Sawyer, of Whistler; but with every care in making the solution and in its administration, he had, while readily getting its constitutional effect, produced sloughing in every case.

Quite a number of the members present had used cinchonidia successfully in their practice, though they had not relied upon it to the extent of Dr. Sholl; using it in the milder attacks, and where it was desirable to consult economy.

DR. WEBB had used it frequently in the usual forms of malarial fever, but had never used it hypodermically. For a number of years he had used in this way either the bromide or sulphate of quinia, without having produced ulceration. His method of preparing the sulphate for hypodermic use, was that recommended by Dr. George Kumpè, of North Alabama. He dissolved sixty grains of sulphate of quinia in one ounce of distilled water by slowly adding dilute sulphuric acid until the solution was clear. To remove any excess of acid he then added five or ten grains more of quinia. This was then passed through a

double filter, which removed all the undissolved crystals of quinia, and gave a clear, *neutral* solution. He had frequently used the sulphate prepared in this way without any unpleasant local effects.

THE PREVAILING CONTINUED FEVER.

DR. SHOLL then gave his views of the nature and treatment of the *continued form of fever*, which has prevailed for the past two or three years in Sumter and other parts of the State. He regarded it as typhoid fever proper; the enteric fever of Dr. Wood and other writers. He had in a number of cases used very successfully, the treatment recommended by him in a paper read before the Medical Association of the State of Alabama, at its meeting in Mobile in April, 1882, entitled "A Proposed Method of Abbreviating the Duration of Curable Cases of Typhoid Fever." His plan was, when meeting a case of suspected or recognized typhoid fever, to give (more properly and hopefully during the first ten days) at once to an adult, forty drops of laudanum per orem, or its equivalent of morphia hypodermically, and follow in one hour with forty grains of ipecac. This dose was administered twice in twenty-four hours, diminishing the dose daily, when the symptoms were more favorable, or discontinuing it, if it failed to produce the desired effect. So far its results have been very happy when tested with parallel cases in the same house under different treatment. The unpleasant symptoms being greatly ameliorated from the beginning of this treatment, and the *duration* of the attack having been brought down in cases which seemed threatening, to seven or ten days; and not prejudicing the results where other treatment was afterwards required.

In those cases in which this plan of treatment did not prove speedily successful, in which the fever continued into the third or fourth week, assuming a more adynamic type, he had used, with good results, the iodide of potassium. He gave it in conjunction with the syrup of lacto-phosphate of lime, four grains of the former to a tablespoonful of the latter, every three or four hours, to which, on the suggestion of Dr. Moody, of Pickens, he had latterly added two drops of carbolic acid, as an antiseptic.

As to the nature of typhoid fever, he was not satisfied to accept the theory of a specific germ, or bacteria, as the sole cause. He had been unable to trace the present epidemic to any foreign source. Impure drinking water, in one instance the constant effluvia of rotting cabbages, the washing of the soiled bedding in another, and the inhalation of the odor of excrement, were deemed sufficient cause for the origin of this disease as seen by him, which, through its soiled linen and foul excreta, transmitted to others what was essentially and only a pure typhoid fever, and whose further ravages in two families was stayed by change of drinking water.

DR. R. D. WEBB, of Livingston, was not prepared to fully admit that the continued fever prevalent in this county, designated variously as continued malarial fever, typho-malarial fever, and typhoid fever, was typhoid fever (enteric fever of Dr. Wood). The variety of names by which it is designated shows the unsettled state of medical opinion as to its real character. Its prevalence in Sumter and other parts of Alabama gives it, to us, a local interest, independent of the etiological and pathological features which it involves. His observations upon the fevers of this county, extending over a period of thirty years, had left doubts upon his mind as to its character.

The changes in type which fevers have undergone in this county from its settlement in 1832–33 to the present time, are well known to all who have practised here for any considerable time. The severity of the cold stage, shortness and high grade of the fever, and subsidence with profuse perspiration and long intermissions or decided remissions, were characteristic of the fever of that day. These symptoms have gradually changed, until now the cold stage is hardly perceptible, the fever protracted and of low grade, the remission very short, and the profuse perspiration has dwindled to a mere moisture of the surface. From this to *continued malarial fever*, with its morning remissions, was but another step in these changes. He here gave a clinical analysis of several cases, with bedside notes, and charts of temperature and pulse, of several cases of what he regarded as continued malarial fever, and called attention to the difference of the phenomena in these and in a true typhoid fever.

In the prevalent fever we have a moist, broad tongue, coated with a white fur, rarely becoming, even in the severe cases, red, pointed, dark or dry; severe bilious vomiting in the outset of the attack; constipation, as contrasted with diarrhœa; flat abomen, and absence of tympanites, and tenderness over iliac region; absence of the rose-colored spots; too great a range in temperature curve, and decided indications of hebdomadal periods which corresponded with the well-known habit of recurrence of malarial fever at the end of the seventh day and its multiples.

Post-mortems in several cases revealed only an hyperæmic condition of the mucous membrane of the intestines, particularly of the ileum, with enlargement of the solitary glands or prominences of the follicles of Lieberkuhn.

In one case he had found ulceration of Peyer's patches, but from the circumstances of the origin of this case, being one of ten others in a local epidemic, evidently due to the unsanitary condition of an adjoining badly drained lot and filthy slaughter-house, he was disposed to regard this also as malarial fever. Pathological observations show that Peyer's glands are often ulcerated in other diseases than malarial fevers. They are from their structure—"solid aggregated masses of nuclear particles"—very liable to enlargement and ulceration, and we may reasonably expect them to be found ulcerated in any disease in which we have a hyperæmic condition of the mucous membrane of the intestines. Hence the ulceration of Peyer's patches is not to be regarded as pathognomonic of typhoid fever.

The question of the etiology of typhoid fever is also involved here. Does it originate, as implied in the remarks of Dr. Sholl, from unsanitary surroundings, *de novo*, or must we have the pre-existing ovum—the *contagium vivum*—introduced from a previously existing case which finds its congenial nidus for propagation in these unsanitary surroundings?

The question is one of vital importance. His observations and studies had led him to favor the view of a previous ovum. The epidemic of typhoid fever which prevailed in this county from 1845 to 1855, which exhibited in a marked degree the characteristic phenomena of typhoid fever, was well known to be due to importation from Virginia, by a company of negroes brought here for sale. So far as he had been able to determine, no such foreign origin could be found for the present fever. Upon the other hand, it occurred sporadically in isolated cases in every part of the county and State, wherever malarial fever prevailed, and did not exhibit any evidences of a contagious nature.

Nor was he disposed to regard the fever as seen here as a hybrid of typhoid and malarial fevers. The possibility of such a hybrid he did not deny; but did not see the evidence of it here. It is, as already pointed out, deficient in the characteristic phenomena of typhoid fever, and if a hybrid, these should be fully manifested, at least in the latter stages.

It presents, so far as his observation goes, nothing of the specific and contagious nature of typhoid fever, but upon the other hand, occurs in isolated cases where none but a miasmatic origin can be traced, which points to its being *endemic* and malarial. The symptoms, or peculiar type too, are satisfactorily explained upon the hypothesis of the changed type of malarial fevers, and hence he did not see the necessity of calling in a new name or fever.

His treatment had been based upon his views of the nature of the fever. At the outset a mild purgative of calomel, and later in the disease enemeta, or laxatives when the bowels need moving. Quinia in the first week, to interrupt as far as possible the paroxysmal character of the fever, and later in the attack, at the hebdomadal periods, for its anti-paroxysmal and anti-pyretic effects. He did not, however, give it in the large doses of some, for its decided anti-pyretic effect, believing that the nervous system was in too irritable a condition to bear these depressing doses. He rarely gave more than thirty grains in twenty-four hours, and preferred giving this in divided doses, of five grains each. He relied mainly upon sponging the surface with cold water to reduce the temperature. He also in the second week, gave salicylate of sodium, tincture of iodine, and carbolic acid. If the tongue was disposed to be dry, and there was tympanites, he used internally spirits of turpentine, and also used it externally over the abdomen, by embrocation or as a stupe. In cases where the pulse was rapid and firm, he used tincture of veratrum viride.

DR. GILMORE, of Gaston, had abandoned the idea of a hybrid, or typho-malarial fever, and was disposed to regard the prevalent fever of our county as continued malarial fever.

DR. J. M. GODFREY, of Sumterville, did not think he had met with typhoid fever since 1860, and was also disposed to regard the prevalent fever as a *malarial fever*.

DR. SHOLL then alluded to the

TREATMENT OF DIPHTHERIA.

He urged a careful test of the following method, which he had now used in fifty cases, with a mortality of three, and believed it to come as nearly as any thing could be to meeting the urgent requirements of these cases.

To an adult he administers twenty drops of liquor potassæ every three hours in half a glass of water. Half-way between each dose he gives one to two tablespoonsful of syrup of lacto-phosphate of lime. Proportionate doses are given to children. He uses no local application to the throat internally. Externally he uses bacon rind freely and often applied to the swollen throat, and if the temperature is high, to the whole body. He desired the members to give this treatment a careful practical test.

DR. R. D. WEBB believed there were good grounds for regarding diphtheria as having local origin from a specific bacteria, which specially found its nidus in the membranes of the throat. The disease was thus first local, and afterwards became constitutional.

Hence in treatment he used locally, in the early stages, the following:

℞. Tinct. of iodine, ... ʒij.
Carbolic acid, ... ʒij.
Glycerine, ... ʒiv.—M.

S. Apply to the tonsils and fauces once or twice a day.

He also used, locally, in the form of spray or steam, a 2 to 5 per cent. solution of carbolic or salicylic acid. Internally he used liquor potassæ, as recommended by Dr. Sholl, with the addition of tinct. mur. ferri, and chlorate of potash.

Under the call for "Report of Cases," DR. J. M. HENSON, of Brewersville, reported a case of

PURPURA HEMORRHAGICA,

in a young lady of twenty years, who did not seem to be suffering very much constitutionally. It had continued three weeks, when an acute exacerbation of fever supervened, with jaundiced (orange-yellow) skin, and copious hematuria. The patient died in twenty-four hours after this exacerbation of fever. Query. Was this an attack of hemorrhagic malarial fever, supervening upon the purpura hemorrhagica, or only a hemorrhage from the kidneys, and into the rete mucosum, from the hemorrhagic tendency of the patient, during the occasion of an ordinary remittent fever?

DR. SHOLL was disposed to regard the diagnosis as doubtful, but probably a combination of purpura with hemorrhagic malarial fever, a few cases of which have been seen in the County this fall.

DR. WEBB reported a

COMPOUND FRACTURE OF THE RADIUS AND ULNA.

treated by antiseptic *closed dressings*, which he saw in July last in consultation with Dr. J. F. Moore. The external wound healed kindly with but little suppuration, and the bones united in the usual time. He was disposed to give the method further trial, as he did not see why we may not in this way secure primary union of the soft parts, and make the cure more speedy, and with less pain to the patient, and less trouble to the surgeon, than by the more usual method of open dressing. He referred in this connection to two cases of compound fracture of the tibia, treated in a similar way, and also to Prof. E. von Bergmann's method of treating compound fractures of the *penetrating variety* by primary antiseptic occlusion. He did not see why we may not apply the same principle to fractures with a greater degree of laceration of the soft parts, especially in the pure air of the country. He believed, even in cases of severe laceration, the wound might be kept to a great degree aseptic, and treated with better success by this method than the open plan.

DR. SHOLL suggested the plastic splints of Koehler, which by warming may be readily moulded to fit any part of the body, instead of the plastic bandage, for these cases. They are convenient and could be readily removed and reapplied, when necessary to renew the dressing.

The lateness of the hour prevented further discussion of medical topics.

The following officers were elected for the ensuing year:

President.—R. H. ARRINGTON, M.D.
Vice-President.—J. B. HAWLEY, M.D.
Secretary and Treasurer.—R. D. WEBB, M.D.

MEDICAL ASSOCIATION OF CENTRAL NEW YORK.

Fifteenth Semi-annual Meeting, held at Rochester, November 21, 1882.

The Fifteenth Semi-annual Meeting of the Medical Association of Central New York, was held at Rochester, on Tuesday the 21st of November, the President, Dr. THEODORE DIMON, of Auburn, in the chair.

After the reading of the minutes of the last meeting, by the Secretary, Dr. J. N. Arnold, of Clyde, the following committees were appointed by the Chair:

On Credentials.—Drs. Bennett, of Livingston; Colvin, of Wayne; and Rider, of Monroe.

Business.—Drs. Kendall, of Onondaga; Jewett, of Ontario; and Hovey, of Monroe.

Reception.—Drs. Dann, of Monroe; Van de Warker, of Onondaga; and Cotes, of Genesee.

Ethics.—Drs. Ames, of Livingston; Slocum, of Onondaga; and Pomeroy, of Cayuga.

Publication.—Drs. Arnold, (ex-officio); Hamlin, of Cayuga; and Roe, of Monroe.

DR. JASON PARKER, of Clyde, then reported a case of

EXTRA-UTERINE CONCEPTION FOLLOWED BY PERITONITIS.

He first saw the case on September 24th, and the next day Dr. Smith, of Clyde, was called in consultation. The diagnosis was peritonitis complicated with cellulitis. The bowels were constipated and there was much tympanites. An enema was given on the 29th. October 1st, there was a severe diarrhœa. The case was one of unusually severe peritonitis, and was treated mainly by large doses of morphia hypodermically; ¼ grain was given every two hours. On one occasion two grains were given in an hour and a half. At another time during the treatment eight grains were given in twenty-four hours.

From October 4th to 16th the patient was doing well, and about the latter date the tympanites had nearly disappeared and the morphia was discontinued. The menses appeared October 8th. There was from the first a hard, circumscribed mass felt in the left inguinal region. The patient died very suddenly on October 17th.

An *autopsy* was made twenty-four hours after death. The abdomen only was opened. There was an unusual amount of adipose tissue. The omentum was greatly discolored and firmly adherent to the peritoneum and the intestines; the latter showed the effects of beginning mortification. The cavity was filled with clotted blood and serum. In the anterior wall of the uterus there was a fibroid tumor about the size of an orange. The right ovary and tube, etc., were normal; at the left of the uterus was a tumor which appeared to take the place of the left Fallopian tube and ovary. On attempting to enucleate the tumor it was ruptured and disclosed a fœtus of about three months.

DR. JOHN GERIN, of Auburn, presented a paper on *Abnormality of the Stomach.*

DR. CHEESEMAN exhibited a brain tumor and narrated the history of the case.

DR. F. M. HAMLIN, of Auburn, read an elaborate essay on

OPIUM SMOKING.

He described the method of preparing the watery extract, and how it was sold. He referred to the absurd popular ideas of the mode of smoking, and described the usual manner and the pipe. He considered the habit one of the most pernicious of vices, for it was not resorted to for the purpose of allaying pain, but simply for sensual pleasure. It stimulates the sexual appetite, and the habitues endeavor to draw all others into the habit. Especially is it used for the purpose of seducing young girls; and as all moral sense is perverted the most atrocious crimes are concocted while indulging in the vice of opium smoking.

He gave statistics showing the number using the pipe, and the amount of opium smoked.

DR. W. J. HERRIMAN, of Rochester, read a paper *On the Care of the Insane.*

DR. L. A. WEIGEL, of Rochester, reported a case of *Chorea Complicating Pregnancy.*

DR. J. E. CARR, of Jordan, made some remarks on

THE TREATMENT OF FRACTURES OF THE LONG BONES,

and exhibited apparatus. He claimed that by subjecting the limb to a continual extension and counter-extension for four days, the muscles would be so stretched that the fractured ends of the bone would slip into their normal position, and the limb could then be dressed in the ordinary manner, and a perfect union obtained.

DR. TOWNSEND claimed that by the aid of chloroform he could in one minute reduce a fracture as well as Dr. Carr could by his method in four days.

DR. HENRY claimed that the muscles could not be stretched, and Dr. Carr maintained that they could be, by gradual extension.

DR. E. M. MOORE stated that some years ago one of his students experimented on this subject of stretching the muscles, extensively. He procured a number of sheep, and before killing them, the tendons were carefully dissected from the region of the foot, and the muscles subjected to powerful tension. It was found that these small muscles would sustain a weight of 300 pounds before tearing, and even then the scapula would sometimes break first. Subjected to such a force these muscles would stretch about three-fourths of an inch. Dr. Moore did not believe that any ordinary force could stretch an adult human muscle.

DR. CREVELING, of Auburn, exhibited drawings of some cases of *Laryngeal Disease.*

DR. H. D. DIDAMA, of Syracuse, read a paper on *The New Factor in Tuberculosis.*

DR. JAMES CHAPMAN, of Medina, read a paper on *Supra-Condyloid Amputation at the Elbow-joint.*

The consideration of the new Code of Ethics was then introduced by Dr. W. S. Ely, of Rochester, who advocated the entire abolition of all codes. The hour being late, and many members of the Society who desired to participate in the discussion being obliged to take the afternoon train, the further consideration of the subject was indefinitely postponed.

DR. CREVELING exhibited a case of

COMPOUND FRACTURE OF THE FEMUR,

where he had sawed off about an inch of the bone above the knee. There was good union, and apparently no shortening. Dr. Moore was sceptical, and measured the limb in presence of the Association, and pronounced the shortening about an inch.

DR. J. O. ROE had a carefully prepared paper on *HayFever; its Etiology, Pathology, and Treatment.* but owing to the lateness of the hour he only gave a short synopsis of it.

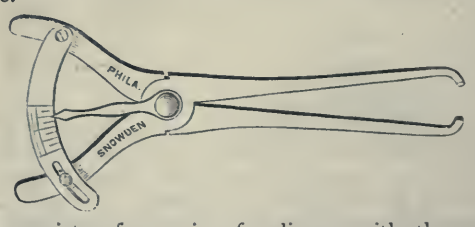
The Association then adjourned, to meet at Syracuse, on the third Tuesday in May, 1883.

NEW INVENTIONS.

THE SEPTOMETER.

BY CARL SEILER, M.D.,
OF PHILADELPHIA.

THE accompanying cut represents an instrument which I have lately devised for measuring the thickness of the nasal septum, and by means of which a differential diagnosis between localized thickening, as exostosis and deviation of the septum, can be made more readily and accurately than by inspection of the nasal cavities alone.



It consists of a pair of calipers, with the points rounded off and turned inward, the blades of which extend beyond the joint and carry a divided arc. Over

the pivot of the joint of the upper blade is fastened a hand, which when the instrument is closed points to the O mark on the arc, and moves toward the right as the points are separated. The joint is moved so easily that the slightest pressure upon the points of the blades separates them, while they are held together by a delicate concealed spring, so that when the portion of the septum grasped between the points presents any variations in thickness, as the instrument is passed up or down, the index hand travels to the right or to the left over the arc, thus indicating the position of the variations. The septometer is held by a wooden handle, screwed at an angle into the lower blade, so that the hand is below the patient's nose, and does not obstruct the view of the points, and also in order to prevent any embarrassment of the delicate motion of the blades by grasping them too tightly.

As a matter of course this intrument can be used for a variety of purposes, where it is desirable, to measure the thickness of tissue.

The septometer is made by Mr. Wm. Snowden, surgical instrument maker, of this city.

(*From Our Special Correspondent.*)

THE JOHNS HOPKINS MEDICAL SCHOOL.—The Trustees of the Johns Hopkins Hospital have, it is understood, recently determined definitely to open the hospital in 1885. There comes to the front, therefore, for the University trustees (a distinct corporation), the question of organizing a medical school which shall coöperate with the physicians and surgeons of the hospital in promoting the advancement of medical science. Such coöperation for such purpose was the express desire of the founder of both Hospital and University. It is hoped, therefore, that the medical school will not enter upon competition with other schools as to number of students, but will put its main strength to the work of giving advanced instruction to men from other schools who already possess the degree of M.D.; and that not being dependent upon students for its support, it will refuse to accept undergraduate students who cannot pass an entrance examination which shall be calculated to decide, at least, whether they have such a general education as may be expected in a professional man, and a fair knowledge of physics, chemistry, physiology, and mammalian anatomy. Such men would be ready to enter at once upon the professional study of medicine in a manner which the average medical student is not. In addition, it is hoped that the Johns Hopkins Medical School will build and support special laboratories for advanced study and research in pathology, pathological anatomy, experimental therapeutics, hygiene, etc.; and so contribute to the advance of medical science in the United States; this was certainly what Johns Hopkins wanted it to do.

THE NEW BIOLOGICAL LABORATORY OF THE JOHNS HOPKINS UNIVERSITY now has its walls completed, and will very shortly have its roof on. Internal fitting up will, however, occupy a considerable time, so that the biologists hardly expect to move into it for some months to come.

The building is of Baltimore pressed brick, with trimmings of bluestone, and is remarkable for the number of its windows. The architect grumbled somewhat at these, as impairing the beauty of his original design; but Prof. Martin insisted that a laboratory should be built like a factory, with just enough wall between the windows to carry roof and floor steadily, and the trustees supported him. The aspect of the building, so far as can be judged at present, shows that the architect's fears were groundless; it has not only that special beauty due to fitness for its purpose, but is (apart from all consideration as to its use) an ornament to the city.

The laboratory is 80 by 54 feet, and consists of a basement and three stories. Its ends face north and south, and the main entrance is placed on one side so as to avoid using up, in doors and windows, space on the north end where the best light for microscopic work was to be obtained: entry from the south was not practicable. The basement is well lighted, so that the rooms in it are available for work-rooms; and, as the building will be heated by hot air supplied from the neighboring chemical laboratory, but little of the basement space is taken up by heating apparatus.

The building is designed to provide for undergraduate students desiring to obtain a thorough practical knowledge of the elements of botany, comparative anatomy, physiology, and histology. Also to afford accomodation for a smaller number of advanced workers in botany, and (in connection with the marine laboratory of the University) for advanced students in comparative anatomy and embryology; but, in view of the fact that the University will soon have a medical school connected with it, very special opportunities have been provided for advanced study and research in animal physiology and histology.

Without going into details, the general arrangement of the building may be briefly described as follows: In the basement is an engine-room, containing also a cremation furnace for organic débris. The engine will work an elevator running from basement to top-story, and will probably be also employed in connection with a dynamo, to supply energy for running the various recording instruments, and for providing electric light in the photographic and histological rooms. The basement will also contain a room fitted up for work in chemical physiology, one for gross dissections and for post-mortems on the animals used in researches; a storeroom for chemicals, glassware, etc.; a battery-room, from which wires can be carried all over the building through special passages leading to each floor, and wide enough to allow a workman to climb through them. In the battery-room will be placed a clock making electric interruptions once a second, and wires will be carried for chronographic purposes from it to any desired part of the building.

The first floor is mainly occupied by a general laboratory for undergraduate work. It also has a lecture-room which will seat about sixty students; a storeroom for diagrams, lecture apparatus, and specimens; an assistant's private room; and a workshop to be fitted up with lathe and carpenter's bench, a glass-blower's table, etc.; in this latter room the laboratory mechanic will have his headquarters.

The second floor will contain a biological library provided with standard works, and the current journals, and proceedings of learned societies from all parts of the world. This room will also be used for drawing figures of specimens and apparatus, and will contain tables specially fitted up for that purpose. On the second floor are also located a small lecture-room, an assistant's room, a laboratory for advanced workers in botany; a similar room for post-graduate work in comparative anatomy; a small museum containing selected animal and vegetable types; and a room for photographing with southern exposure and arrangements for using the heliostat in micro-photography.

The third floor is to be devoted mainly to advanced study and research in animal physiology and histology. In addition to separate laboratories for experiments on warm- and cold-blooded animals, it will contain the professor's private room; a room for myographic experi-

ments and for work on animal electricity; a balance room; and a museum of physiological instruments and chemical preparations.

On the roof will be a small observatory exposed to direct sunlight, and available for printing off photographs, and for experiments as to the influence of solar radiation upon the physiological processes of plants and animals.

It is not proposed to have a room for gas analysis, or a combustion-room in the biological laboratory, as the recent additions to the chemical laboratory close by provide sufficient accommodation of this kind for the biologists.

The new building is calculated to provide ample accommodation for about fifty undergraduate workers, ten advanced students in botany and comparative anatomy, and about twenty advanced workers in animal physiology and histology.

NEW ORLEANS.

(*From our Special Correspondent.*)

Health of New Orleans.—This city has enjoyed a rather remarkable exemption from sickness during the past season. The overflow of the Mississippi in the spring has been followed by intensified malarial diseases in many parts of the valley, and by dysentery in some parts of the overflowed districts. It is true, however, that some portions of the inundated regions have been exempt from all forms of disease not usual to them. The proper explanation of this apparent difference in effect is due to the accidental circumstances affecting the various localities. First, wherever the currents produced by the escaping waters swept the surface, no sickness was likely to ensue. Second, wherever very deep deposits were formed, the circumstances were not favorable to the evolution of malaria. But, third, wherever slight deposits occurred from the stagnant water, violent malarial diseases have prevailed.

New Orleans has not been afflicted with malarial diseases to as great an extent as usual. The same statement is true with regard to yellow fever. Some four or five cases of this disease have occurred during the summer, but no epidemic has resulted. As yet, there is too little known about the essential nature of the yellow fever poison to justify any declaration in regard to the failure of the disease to spread, after having been introduced into this city. It is true, that the locality in which the first cases appeared was inhabited by persons for the most part acclimated by having had previous attacks of the disease. But it can be safely asserted that there is no part of the city, which cannot furnish enough material to set an epidemic going, provided precautions be not taken to prevent its spread. The efforts of the State Board of Health to stamp out the disease, and, probably more than all, the efficient co-operation of the auxiliary Sanitary Association may have had something to do in arresting the spread of the disease. People are apt to talk a good deal about a yellow fever condition of the season, or atmosphere, or some other surrounding, which they are not able to define. There is nothing known peculiar to this season in New Orleans, and certainly nothing which should differentiate it from the conditions in Pensacola in any particular manner.

Pilocarpine in the Treatment of Hydrophobia.—A case of hydrophobia has just terminated fatally in this city, and the treatment presents something of interest. A man, aged about 40 years, had been bitten nearly six months before the attack. His physicians began the treatment with the exhibition of pilocarpine subcutaneously administered. The doses were only one-tenth of a grain each, and repeated from two to four hours. Most profuse salivation resulted, associated with drenching diaphoresis and notable diuresis. The patient's symptoms were not in the least mitigated; on the contrary his medical attendants assert that his thirst was so greatly aggravated that they deplored the use of this drug, since it seemed barbarous to excite thirst in a man who is utterly unable to relieve the sensation. They are all unanimous in declining to countenance further experiments with this proposed remedy for hydrophobia.

The Medical Department of the University of Louisiana has opened its session with promise of a good class.

BROOKLYN.

(*From our Special Correspondent.*)

St. Peter's Hospital.—Dr. P. L. Schenck has been elected attending surgeon at St. Peter's Hospital, in the place of the late Dr. Lowell. Dr. Schenck was formerly for many years the Superintending Surgeon to the King's County Hospital, a patient of which latter institution undertook to assassinate him by shooting, some months since, to avenge some fancied wrongs. Happily the attempted murder failed, and Dr. Schenck has so far recovered from his wound as to be able to accept this new position.

The County Asylum for the Insane.—Dr. J. C. Shaw, Superintendent of the County Asylum for the Insane, has recently made an annual report, showing that the demands upon that institution are constantly increasing. Dr. Shaw is an earnest advocate of non-restraint. There were 1221 patients treated in the year.

King's County Hospital.—Dr. J. A. Arnold has also made a report for the King's County Hospital. He points out the urgent need still existing for a contagious disease hospital on a basis different from that now operating. At the present time all who require hospital accomodations when suffering from contagious affections are on the footing of paupers. There should be some provision made for those who are well-to-do and willing to pay for good diet and attendance, in some building apart from the County Hospital. The Commissioners of Charities are about to introduce gradually the employment of trained nurses; they have appointed fifteen such nurses at a salary of $14 per month. This is unmistakably a move in the right direction.

BOSTON.

(*From our Special Correspondent.*)

Dr. Carpenter on Human Automatism.—Dr. Wm. B. Carpenter, the distinguished English physiologist, is now delivering a course of lectures on human automatism before the Lowell Institute. The first lecture was delivered on Monday evening, November 13, and outlined the theory which will be proved on subsequent evenings. After alluding to the limits of possible knowledge of the nature of man, the lecturer defined an automaton as a machine which has in itself a power of motion under conditions fixed for it, but not by it. In this sense man is an automaton. Advocates of the doctrine of pure automatism assert that the actions of men are solely the result of outward impressions on the nervous system, and that consciousness and will have no more to do with them than the whistle of a locomotive has to do with the progress of the machine. The automatic bellows-blower is an illustration of a pure automaton. The school just named holds that man is just such an automaton, and that a man possessing neither consciousness nor will-

power would, given the same conditions of heredity and environment, act precisely as men now do. The vital defect of this doctrine is that it contradicts the testimony of consciousness, which is the very witness which gives us the facts by which its own evidence is impeached. We are directly conscious of mental phenomena, and only indirectly of the physical, and we can judge of the nature of another human being only by attributing to him the same mental states which, as shown by consciousness, accompany in ourselves the same outward actions. The aim of the lecturer will be to reconcile the testimony of consciousness with the observed facts of physiology and psychology which have given rise to this theory of pure automatism. The relation between mind and body is largely maintained by the nervous system, an apparatus consisting of sensory and motor elements. This twofold nervous system, with the muscles on which it acts, and the mechanical levers moved by them, would make up the whole physical man but for the apparatus necessary first to build up this machine, and afterwards to keep it in health.

The connection between a *neurosis*, or change in the condition of the nervous system, and a *psychosis*, or change in the mental state, is a problem which probably will never be solved.

Prof. Clifford, influenced by preconceived mathematical ideas, was unable to conceive of change in matter as due to anything else than a change in the position or motion of surrounding matter. Prof. Huxley once admitted that neurosis was the cause of psychosis. Now he believes that neurosis can proceed in the absence of mind. The logical result of this theory, as stated by a distinguished adherent, is: "I am what I am, a creature of necessity. I claim neither merit nor demerit, and am no more responsible for my doings than is the needle which turns toward the poles, or the puppet which moves by the pulling of a string." Common sense, the universal testimony of consciousness, revolts at this theory. It contains much truth, but is not the whole truth. Much is due to heredity and environment, but man has a power over the formation of his character and in shaping his course of action, this power arising from his ability to fix his attention upon such motives as he prefers among those arising automatically before him. An important fact is that the greatest results of mental activity are produced by means of some of the smallest of the organs of the body. A famous instance is the case of Laura Bridgman, who, bereft of nearly every sense, was put into communication with the external world by the skill and patience of Dr. Howe. The case of the paralytic who ruled his family by the winking of his eyelids (*Noirtier* in Monte Cristo) illustrates another phase of this truth. The organs of speech, the muscles of facial expression, muscles used in writing, are all comparatively insignificant, and yet by their instrumentality the greatest results of mental force are accomplished. A striking instance was the bombardment of Alexandria following Lord Granville's brief dispatch: "Bombard the forts to-morrow morning." A few movements of the fingers upon a telegraphic instrument brought on a war. So true is it that there is no common measure between our mental and our physical activities. We may measure the waste of nervous matter expended in mental activity, but the "thoughts that breathe and the words that burn," how are they to be measured?

The truth is that mental and physical activity are two distinct spheres which touch each other only at the two points of sensation and motor impulse. The body may be likened to a horse, the mind to the rider who trains and measurably guides it. Thus the body is essentially automatic in all those functions which are concerned in the preservation of life, a control being given to the will—which is not an attribute but the *ego* in action—to modify to a certain extent the action of the body. The phenomenon of respiration affords a useful analogy. During sleep it goes on automatically, the will not being directed toward it, but when we speak, for instance, the will controls the breathing process to a considerable though limited extent. Coughing is a strictly automatic act, but yet may be checked or produced at the mandate of the will. In other words mental impulse is capable of exactly replacing the automatic in directing the action of these organs. From this fact arises the distinction between voluntary and volitionary movements. Thus in taking a walk the legs move automatically, while the mind is engaged in conversation with a companion, but if fatigue asserts itself, the will must step in and compel the continuance of muscular movement, and there are many similar illustrations.

Second Lecture, November 16.—This lecture comprised a general outline of our knowledge of automatism in the lower plants and animals, and thence up to man. Man's automatism is partly congenital, partly acquired; the form considered in this lecture was the former type, which is concerned wholly with vegetative or organic life. Higher than this is the automatism of sensation, higher still, rational automatism.

Commencing with the automatism of plants, the lecturer took up some of the lowest forms of plant life—the green seaweeds—describing the spontaneous movements of the zoöspores. Their motor organs are prolongations of the protoplasm of the plant. Vaucher, the naturalist of the last century, was the first who observed this plant motion. Hence the name of the plants—Vaucheria. He thought these plants were vegetable at one period of their existence, and at another, animal. The leading microscopists forty years since claimed that the plant was an animal. A much higher form of vegetable automatism is seen in the leaves of the sensitive plant, or in the action of Venus's fly-trap. If any leaf of the Mimosa be touched it at once droops and becomes flaccid, but gradually recovers strength and revives again. If any of the spines on the bilobular leaves of the Venus's fly-trap be touched the lobes rise and close, capturing any insect which may chance to be between them. An axis-cylinder of protoplasm extends from cell to cell in these plants and furnishes the connection necessary for automatic action.

Automatism in insects was next considered. The simplest form of animalcula is a cell having a mouth surrounded by ciliæ, which by a to-and-fro waving movement produce currents in the water in which the creature exists. Similar ciliated cells are found in the human body, in the lungs, for example. The amœba, one of the simplest of jelly specks, extemporizes a mouth at that portion of its body which comes in contact with a substance suitable for assimilation. A mouth and exit are both extemporized. Exactly similar bodies are found in our own blood—the white corpuscles. They can be seen taking matter into themselves just as the amœba does. Amœboid cells line the stomach and apparently assist in the assimilation of food. A higher grade of automatism is seen in the jelly-fish, in which there seems to be a separation of the nervous and muscular systems.

The crinoid, to which Dr. Carpenter has devoted special study, was next considered. In its perfect state the crinoid is a starfish with a distinct separation between nerve and muscle. Each arm of the starfish has hundreds of joints, each with its proper muscles of action and opposition, and the creature controls them by means of the nervous system at its centre. Articulated creatures—a centipede being the illustration—were next discussed. Then followed a description of the gan-

glionic system. The simple ganglionic apparatus in a water animal was explained. It has two orifices—one for the ingress, the other for the egress, of a current of water. The animal, probably, has a low degree of sensation, and whenever a solid substance comes in contact with one of the tentacles at the place of ingress, it is at once ejected by an act much like coughing —a good illustration of reflex action. Various other illustrations of reflex action in the lower animals were given.

In man there is an automatic action which continues through life. The act of sucking is perfectly performed by a new-born infant; there is great complication of movement, but it is wholly automatic. In puppies the cerebrum has been removed, and the act of sucking continued as perfectly as before. The act of swallowing is purely reflex. By an act of the will the food is carried to the lower muscle of deglutition, and they then act automatically. The stomach acts automatically in bringing food from its interior to its coats. The action of the pyloric valve is also automatic, as are the peristaltic movements of the intestines. The heart's action is likewise automatic, and thus it is seen that the important functions necessary for the preservation of life are carried on without our consciousness. The whole life of the lower animals is automatic.

CANADA.

(*From our Special Correspondent.*)

DR. DICKSON, OF KINGSTON.—Another of the Canadian Medical Schools has lost its senior member and presiding officer. Dr. Dickson, President of the College of Physicians and Surgeons, of Kingston, Ontario, died on the 23d, after a prolonged illness. The deceased was a native of Ireland, and began his professional studies at Belfast and Glasgow. He was a graduate of the University of New York (1842), and a member of the Colleges of Physicians and Surgeons of London. He was one of the founders of the Medical School at Kingston, and the Professor of Surgery, and President of the Faculty. For nearly ten years he occupied the position of Superintendent of the Insane Asylum. He was the first president of the Ontario Medical Council.

DIPHTHERIA IN PHILADELPHIA.—The deaths from diphtheria in Philadelphia for the week ending November 25th amounted to 29, a falling off of 10, or a decrease of about 25 per cent., as compared with the number for the preceding week. In the corresponding week of last year there were 21 deaths from this cause. For the month of November (to November 25th) there have been 103 deaths reported, which is an excess over the number recorded in any preceding month. The number of cases reported at the Health Office to November 27th, is 276, which represents an increase; but these figures show a laxity on the part of physicians in reporting cases, as required by law; otherwise the mortality would be unprecedented.

In comparing the cartographic illustrations of the prevalence of the disease as indicated by the deaths in 1882 with the year 1881, it is observed that there is a striking agreement in the periods of the rise and fall of the mortality; only that the lines in 1882 are more pronounced than in 1881. There are two periods of maximum mortality, namely, in the first and last periods of the year, and one of the minimum mortality which is reached between the end of the winter and the first of the fall months. The fall and winter months appear to be those in which the disease is most rife.

The disease appears to be confined almost exclusively to children; not a death is reported, during the past week, among adults.

Cases are reported in twenty-eight out of the thirty-one wards of the city. While the disease is thus generally distributed, the returns show that it is most prevalent in Frankfort, an outlying district.

In some instances the disease is reported as malignant in character; as many as three children dying in one family.

By an Act of Assembly, physicians are obliged to report all cases of diphtheria to the Health Office, as soon as they come to their notice, under a penalty not exceeding fifty dollars for violation of this provision of the law. This act has not hitherto been generally complied with. Its object is to furnish the authorities with the earliest information of the existence of the disease, that prompt action may be taken to restrict, if not prevent, the spread of the disease.

The Board of Health have published for distribution, a series of rules on the restriction and prevention of diphtheria, which appear in another column. This plan has been generally adopted in regard to other contagious diseases, and is to be commended in this case. As this disease is chiefly one of childhood, it is safe to assume that it is often communicated by the intercourse of children in the early stages of the disease, or from infected houses with others in the public schools and other places. It is, therefore, eminently proper that parents should be carefully instructed in their duties in this respect, and in all measures to restrict the spread of the disease.

SANITARY INSPECTION OF NEWPORT, R. I.—The Sanitary Protective Association of Newport, R. I., met on the 24th of Nov. to act upon the Report of the Sanitary Survey of the city, made under the auspices of the National Board of Health, by MR. E. W. BOWDITCH, of Boston, Mass. The report gives a general statement of the character of the results obtained by the inspectors. Over 2,000 surveys were made, the reporter's notes of which are in the hands of the Association, and available for immediate and practical use. Maps and charts accompany the reports, exhibiting by different shades of color, and by the number of degrees of a circle thus shaded, the percentages which were obtained. Thus, as to cellarage: the per cent. of good, fair, and bad cellars in the whole city is first shown, and then the ratios in each of the wards. Another series of drawings represents the relations of the privies and cesspools to the wells. We understand that it is not proposed at present to publish either the report or charts for general distribution. From the *Fall River Daily Herald* of November 24th, we learn that "The investigation was made at the request and expense of the Society [Sanitary Protective Association, Newport] to influence the city authorities to establish a separate health board, and it was offered to suppress the report if such a board were established. The proposition was refused, and it is probable that the full report will soon be given to the public.

CHOLERA AMONG THE PILGRIMS.—Official advices to the National Board of Health announce that cholera made its appearance among the pilgrims at Mecca, on October 24th. On the 29th, there were 48 deaths among them from this disease. As this is the time of the greatest afflux of pilgrims to the Holy Cities, and as they will shortly be commencing their return journey, it is justly apprehended that the disease may be spread by them with disastrous results. Vessels coming to Suez are strictly quarantined by the Sanitary Administration of the Ottoman Empire; thus the danger of the introduction of cholera into Europe, by way of the Red Sea, is considerably lessened; but the overland caravans may scatter the seeds of the disease, and bring them to the Mediterranean by unguarded routes.

Prevention and Restriction of Diphtheria.—The Philadelphia Board of Health has just issued the following circular on this subject:

Recent investigations having proved that the poison of diphtheria is portable, communicable by infection, and capable of reproducing itself outside of the human body, diphtheria must now be ranked as both a contagious and infectious disease. The following rules are therefore more imperative than ever before:

First. When a child or young person has a sore throat, a bad odor to its breath, and especially if it has fever, it should immediately be separated and kept secluded from all other persons except necessary attendants, until it be ascertained whether or not it has diphtheria, or some other communicable disease.

Second. Every person known to be sick with diphtheria should be promptly and *effectually isolated* from the public. Only those persons who are actually necessary should have charge of or visit the patient, and these visitors should be restricted in their intercourse with other individuals. Children residing in a house where there is a case of diphtheria should not be permitted to attend school.

Third. When a case of diphtheria is fully developed, the same precautions in regard to free ventilation, disposal and disinfection of discharges, bed or body linen, and so forth, isolation during convalescence (or management of the corpse should death unfortunately occur), etc., ought to be enforced which have already been recommended in regard to smallpox.

Fourth. It is particularly important that persons whose throats are tender or sore from any cause should avoid possible exposure to the contagion of diphtheria. Children under ten years of age are in much greater danger of taking the disease, and after they do take it of dying from it, than are grown persons. But adults are not exempt, and mild cases in them may cause whole series of fatal attacks among children.

Fifth. Numerous instances are recorded where the contagion of diphtheria has retained its virulence for weeks or months, in cesspools, heaps of decaying vegetable matter, damp walls, etc., and been carried for long distances in clothing, in sewers, in waste pipes from stationary wash-stands, and in other conduits. Hence all sewer connections and other carriers of filth should be well ventilated and disinfected, and children particularly should not be allowed to breathe the air of any water-closet, cesspool, or sewer into which discharges from patients sick with diphtheria have entered, nor to drink water or milk which has been exposed to such air.

Sixth. Beware of any person who has a sore throat; do not kiss such a person or take his or her breath; do not drink from the same cup, blow the same whistle, nor put his pencil or pen into your month.

Seventh. Do not wear nor handle clothing which has been worn by a person during sickness or convalescence from diphtheria.

The Bacilli of Tubercle only Fat-crystals.—At a meeting of the Pathological Society held at the Charity Hospital, New Orleans, on Nov. 20th, Dr. H. D. Schmidt, President of the Society, made a demonstration with the aid of the microscope to test the alleged discovery by Prof. Koch, of Berlin, of the bacilli of tuberculosis, or the germs of consumption. Dr. Schmidt has devoted much time to the observation of the bacilli of tuberculosis, and while engaged in his researches the discovery of Dr. Koch was announced to the world. This only encouraged Dr. Schmidt to renewed efforts, and the result was that he ascertained, beyond doubt, he claims, that Dr. Koch's germs were pseudo-bacilli, that is, fatty crystals, and not true bacilli. This result, it was stated, was obtained by long and arduous labor, in which the diseased organs of persons that had been afflicted with pulmonary consumption were minutely and carefully examined. Dr. Schmidt succeeded in finding the crystals, which were similar in appearance to those discovered by Koch, and evidently the same. To determine their nature, Dr. Schmidt subjected the crystals to the action of boiling ether, when they disappeared, proving that they were not germs or organisms, otherwise they would have remained unaffected by the ether.

Dr. O. W. Holmes has been appointed, by the President and Fellows of Harvard University, Emeritus Professor of Anatomy, in consideration of his many valuable services in the medical school during the past thirty-five years. He delivered his farewell anatomical lecture on last Tuesday.

DaCosta's Diagnosis.—A German translation of this well-known American work has just been issued by Hirschberg, of Berlin.

Suspension of the Archives of Dermatology.—It is announced that the *Archives of Dermatology* a well known quarterly journal, edited by Dr. L. Duncan Bulkley, suspends publication after the appearance of the number for the present quarter.

The Lancet's Libel Suit.—We are glad to hear that the Corporation of Brighton have abandoned the action for libel which they had commenced against the *Lancet*.

The "Pharmacopœia Germanica" for 1882.—The German Pharmacopœia has been subjected to revision, as is usual every ten years, and is now ready for distribution. Many articles included in early editions, and now proved to be worthless, have been discarded, and the new drugs receive full attention, so while the edition of 1882 considers more than 300 articles less than that of 1872, the space remains nearly the same. It is written in Latin.

Jefferson College Hospital.—Drs. Joseph Hearn and O. H. Allis, have been elected surgeons to the Jefferson College Hospital, in Philadelphia.

The New York Society for the Relief of Widows and Orphans of Medical Men has just published its 20th Annual Statement, from which it appears that the society now numbers 142 members, of whom 94 are for life and 48 annual subscribers. There are also 22 benefactors, constituted by the payment of $150.00. During the past year $4,288.00 were paid to annuitants and its present assets are $141,249.49.

Charges against Prof. Frothingham, of the University of Michigan.—The Medical Faculty of the University of Michigan have just considered the charges made by student Morgan against Prof. Frothingham, of attacking the Christian religion, and the counter-charges of falsehood by Prof. Frothingham against Morgan. The Faculty, on Nov. 24th, decided that as to Prof. Frothingham they had no jurisdiction, but that the charges of the latter against Morgan were not sustained. This is claimed to be a victory for Morgan against Prof. Frothingham, and it is stated that the matter may now be taken into consideration by the Board of Regents as against the Professor.

Rotunda Lying-in Hospital.—Dr. A. V. Macan has just been elected master of this well-known institution, to succeed Dr. Lombe Atthill, whose term of service has expired.

EDINBURGH UNIVERSITY.—It is said that there are three hundred more students in Edinburgh this year than last.

DR. FRANCIS SEYMOUR HADEN, the eminent English etcher and surgeon, now on a visit to this country, was the guest of the St. Botolph's Club, in Boston, last Saturday evening.

A SUIT FOR MALPRACTICE AGAINST THE LONG ISLAND COLLEGE HOSPITAL.—A suit to recover $25,000 as damages for unskilful treatment of a broken leg, brought by Carl Elbe against the Long Island College Hospital, came to trial this week, in the Circuit Court, before Judge Gilbert. The plaintiff alleges that he went to the hospital with one leg broken on May 29, 1880, and by malpractice his leg was permanently shortened, and he was crippled for life. The hospital authorities made a general denial of the charge of improper treatment. The case is still on trial.

THE PARKES MUSEUM OF HYGIENE.—This museum has been incorporated by Act of Parliament and has recently acquired quarters in Margaret Street, Regent Street (opposite the Church of All Saints). On October 28th, the first general meeting was held and His Royal Highness, Prince Leopold, Duke of Albany, was formally elected the first president.

THE COLOR BLIND.—According to the *British Medical Journal* the Swedish Government has decided to employ no individual on railways, or on board ship, in that country, until he has successfully passed Prof. Holmgren's test of color-blindness.

HEALTH IN MICHIGAN.—Reports to the State Board of Heath for the week ending Nov. 18, 1882, indicate that typhoid fever, pneumonia, and neuralgia have increased, and that bronchitis, tonsillitis, typho-malarial fever, diphtheria, intermittent fever, cholera morbus, diarrhœa, and scarlet fever, have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending Nov. 18, and since, at 24 places, scarlet fever at 13 places, and measles at 3 places. Smallpox was reported at Niles and at Grand Rapids, Nov. 18.

OBITUARY NOTICE.—DIED, on October 26th, PROF. OBERNIER, of Bonn, in the 44th year of his age. Prof. Obernier was born in Bonn, in 1839, where he obtained his medical degree in 1858, his dissertation on the nerves of the uterus receiving a prize. He was soon appointed an assistant at the university clinic, and succeeded Prof. Rühle as ordinary Professor of Medicine in the Bonn University. He was called to Jena but he preferred to remain in his native university-town. He served through the Franco-Prussian war, and was decorated with the iron cross. He was the author of the Section on Diseases of the Brain in Ziemssen's Handbook.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 20 TO NOVEMBER 27, 1882.

ALDEN, CHARLES H., *Major and Surgeon.*—At expiration of present leave to report to the commanding general, Department of Dakota, for assignment to duty.—*S. O., par. 10, No. 273, A.G.O., November* 23, 1882.

BILL, JOSEPH H., *Major and Surgeon.*—At expiration of present leave to report to the commanding general, Department of the Platte, for assignment to duty.—*S. O., par. 10, No. 273, A.G.O., November* 23, 1882.

MCKEE, JAMES C., *Major and Surgeon.*—Now awaiting orders, is assigned to duty in the Department of California.—*S. O., par. 10, No. 273, A.G.O., November* 23, 1882.

SMITH, ANDREW K., *Major and Surgeon.*—At the expiration of his present sick leave will be assigned to duty at Willet's Point, New York.—*S. O., par. 10, No. 273, A.G.O., November* 23, 1882.

BARNETT, RICHARDS., *Captain and Assistant Surgeon.*—The leave of absence granted November 1, 1882, is extended five months.—*S. O., par. 11, No. 273, A.G.O., November* 23, 1882.

BROWN, PAUL R., *Assistant Surgeon.*—The leave of absence granted May 25, 1882, is extended six months on surgeon's certificate of disability.—*S. O., par. 7, No. 273, A.G.O., November* 23, 1882.

CLEARY, PETER J. A., *Captain and Assistant Surgeon.*—Now awaiting orders, will report to the commanding general, Department of Dakota, for assignment to duty.—*S. O., par. 10, No. 273, A.G.O., November* 23, 1882.

CORSON, JOSEPH K., *Assistant Surgeon.*—Is assigned to duty at Jefferson Barracks, Missouri.—*S. O., par. 8, No. 273, A.G.O., November* 23, 1882.

MUNDAY, BENJAMIN, *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Willet's Point, New York, and assigned to duty in the Department of the Columbia.—*S. O., par. 10, No. 273, A.G.O., November* 23, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE MARINE-HOSPITAL SERVICE, JULY 1 TO SEPTEMBER 30, 1882.

HUTTON, W. H. H., *Surgeon.*—To inspect keepers and crews Life-Saving Service, July 11, 1882.

MILLER, T. W., *Surgeon.*—To inspect keepers and crews, Life-Saving Service, August 7, 1882.

WYMAN, WALTER, *Surgeon.*—To inspect keepers and crews, Life-Saving Service.

LONG, W. H., *Surgeon.*—Granted leave of absence for ten days, July 1, 1882. Granted leave of absence for fourteen days, September 16, 1882.

MURRAY, R. D., *Surgeon.*—To proceed to Brownsville, Texas, August 21, 1882.

PURVIANCE, GEORGE, *Surgeon.*—To inspect keepers and crews, Life-Saving Service, July 13 and 18, 1882. To report for temporary duty at Washington, August 23, 1882. To report for temporary duty to Chairman Board of Examiners, Rev. Bk. "Chase," at Norfolk, August 26, 1882.

SMITH, HENRY, *Surgeon.*—Granted leave of absence for thirty days, July 5. 1882.

FISHER, J. C., *Passed Assistant Surgeon.*—To report for temporary duty to Chairman Board of Examiners, Rev. Bk. "Chase," at Norfolk. August 26, 1882.

IRVIN, FAIRFAX, *Passed Assistant Surgeon.*— Granted leave of absence for thirty days, July 28, 1882.

CARTER, H. R., *Passed Assistant Surgeon.*—To proceed to Hickman, Ky., for temporary duty, August 10, 1882. To proceed to Memphis, Tenn., for temporary duty, August 12, 1882. To proceed to Little Rock, DeValls Bluff, and Newport, Ark., as inspector, Sept. 16 and 21, 1882.

PORTER, F. D., *Assistant Surgeon.*—To proceed to St. Louis, Mo., for temporary duty, August 21, 1882. To report to Surgeon Sawtelle for examination for promotion, Sept. 1, 1882. To rejoin his station (Chicago) when relieved by Assistant Surgeon Urquhart, Sept. 1. 1882.

BENSON, J. A., *Assistant Surgeon.*—To proceed to Cairo, Ill., for temporary duty, August 12, 1882.

DEVAN, S. C., *Assistant Surgeon.*—To join Rev. Str. "Corwin," for cruise in Alaskan waters, July 10, 1882.

URQUHART, F. M., *Assistant Surgeon.*—To proceed to Wilmington, N. C., for temporary duty, July 26, 1882. To proceed to St. Louis, Mo., for temporary duty, September 1, 1882.

PROMOTION.

PORTER, F. D., *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon by the Secretary of the Treasury, from October 1, 1882. September 14, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLI. SATURDAY, DECEMBER 9, 1882. NO. 24.

ORIGINAL LECTURES.

ON CERTAIN CUTANEOUS AFFECTIONS OF THE HANDS.

A clinical lecture delivered at the Rush Medical College,

BY JAMES NEVINS HYDE, M.D.,

PROFESSOR OF SKIN AND VENEREAL DISEASES IN THE RUSH MEDICAL COLLEGE, CHICAGO, ILL.

GENTLEMEN: By one of those singular coincidences with which we are made familiar in every public clinical experience, we have here presented to us for study several patients whose hands chiefly are affected with cutaneous disease. Let us begin by passing these cases in review; and then endeavor to understand the sign-language they are ready to teach us.

The first patient is a middle-aged woman in apparently fair health, who complains of an "itching humor which has been out for three weeks on the hands." She tells us that she does all the household work for her husband and three children. When we examine her hands, we observe that both organs exhibit a cutaneous disease, the right rather more than the left. The disorder has involved chiefly the dorsal surfaces and interdigital spaces. Here the integument is irregularly involved, in areas so indeterminate in outline that we could not map out the diseased surfaces with a pen or pencil. The limitation is most distinct as regards the palms, which are absolutely free from invasion. On the dorsal surfaces, chiefly about the metacarpo-phalangeal articulations, there is moderate thickening of the skin, which is of a dull reddish hue, and moreover raised so as to form papular elevations as small as poppy-seeds, very irregularly disposed upon the surface. Islands of sound skin, as indeterminate in outline as the patches of disease, can readily be distinguished here and there over the dorsal surfaces nearer the wrist. There is a little oozing from a few of the papules which have been torn in scratching, and this ooze has desiccated into a few thin and insignificant crusts on the right hand. The disease-process, you see, has extended slightly upward over the forearms, but ceases absolutely about the middle third of each. There is, however, at this limit of extension, no line of demarcation. Straggling papules of poor development, and less reddened patches gradually cease to show at this level; that is all. Her face, too, is reddened; its skin is slightly infiltrated, and she complains also of itching in this region. By passing the finger over its surface, you can here also detect a few very minute papules, and recognize the fact that the skin is here hotter than normal. The outline of the involved area is very indeterminate; we cannot say where the disease process begins and where it ends.

This affection we recognize without difficulty as an illustration of eczema, erythematous and papular in type. Our questions elicit the fact that she has been using a strong solution of washing soda in her laundry-tub, in order to save some of the labor of scrubbing her clothes with her hands; and this caustic solution, she admits, she has also used in washing her face. So much light, then, we have thrown upon the "humor of the blood."

The next patient is also an adult, a fireman, of vigorous appearance, whose hands are carefully wrapped up in greasy rags. He tells us that they have been giving him trouble for nearly a year; that no physician has thus far been able to help him; and that he has no disease of the skin elsewhere. Now that they are uncovered, note how very differently his hands are involved from those we have just seen, not only as regards the site of the disorder, but also with respect to its behavior. The jealousy with which the palms were respected in that case is equalled in this by the absolute immunity of the dorsal surfaces. Here, on the right hand only, a single patch of disease slightly laps over the web stretching between the thumb and index finger, but in no other part is there any approach of the skin affection to the back of the hands.

Both palms, you observe, are involved, and nearly equally, almost symmetrically. Here we have a disease in distinct patches; we can map out each perfectly with a pen. The patches are of the size of half and whole silver dollars; some, nearly as perfectly circular; some oval; one, over the left hypothenar eminence, reniform or kidney-shaped. Look carefully at these curious disks, for each tells its story. In nearly every one, you can make out three levels. First, you see that the outer line of the disk is constituted of an apparently sound epidermis of the palm, clipped sharply and circlewise, as by a delicate pair of scissors, and slightly raised above the first level which it walls in. This rise of the apparently sound epidermis forming the wall, has slightly interfered with its vitality, for it has an unnaturally dead-whitish hue for a brief space around, and can be slightly raised from its bed with the finger-nail.

Next, proceeding towards the centre, is the first level, where is a younger and more tender epidermis, which, because it is thus young and tender, is unnaturally translucent, and permits the color of the inflamed derma beneath to modify its tint. This is why these disks have a dull purplish hue, and not the reddish shade of the hands we lately saw fresh from the laundry tub. But this new epidermis fails us as we pass to the centre of the disk, fails us very irregularly as to its width, but quite regularly as to its curved cuttings, over which we pass to a second level. Here is an epidermis still younger and still more tender, but yet an epidermis, through which, yet more clearly, we get a glimpse of the deep purplish and inflamed corium beneath. Lastly, in the centre, we reach a third and deepest level, which differs in different disks. In some, you see a glazing, over the engorged and empurpled derma; in others, the latter is fissured aud oozing, the fissure extending in a straight crack across the disk, but always at nearly a right angle with the axis of the hand.

These palmar fissures annoy the patient more than any other symptom; and for this reason he has his hands so carefully tied up. He is a right-handed man, and he refers all his troubles to his handling of the hose-pipe when discharging his duties as a fireman.

But we are wiser than he in this matter, and indeed ought to be, seeing that these lesions tells us their own story without aid of his. Nothing but syphilis can explain such a pathological condition of the palms. No eczema, no psoriasis, no scabies, no lupus, no one of the long list of other cutaneous maladies, is ever characterized by the formation of these circular and oval disks, with their frayed epithelial walls and series of rising epidermal plateaux, with central ulcers or fissures. We are quite prepared to hear him therefore admit, as he does with some astonishment when he is

questioned upon that point, that he did have a sore on the genital region six years ago, followed by suspicious symptoms which were at the time "cured;" and that one of the first fruits of his subsequent marriage was an abortion on the part of his wife.

Our next patient is a healthy-looking man who approaches with his hands also carefully wrapped up, and who removes the dressings with extreme care. When exposed to view, we note that both organs are very extensively involved, the right more than the left. The palms are spared but the dorsal surfaces are pretty uniformly affected. The skin is tumid, and resembles a cushion on the back of the hand. The surface here is covered with pin-point sized vesicles, between which serum oozes from floors where evidently other similar lesions have formed and ruptured. Some of these vesicles have clear, others lactescent, contents. Here and there, sparsely found it is true, are small pustules evidently resulting from transformation of the vesicular lesions. A few light yellow crusts are seen on the region about the knuckles. The vesicular lesions extend to the interdigital spaces, where also the skin is swollen, hot and painful.

This is a case of dermatitis venenata. Our patient describes slightly bruising one knuckle of his hand with a hammer: and for the relief of the trivial resulting abrasion, he applied the tincture of arnica freely over the surface. He is sure that he spilled this over both his hands; and the dermatitis was in this way originated. Generally in such cases, the hands of the male carry the offending substance to the genital region, when the penis is handled in the act of micturition. This has been the result in this instance, the skin of the penis and scrotum being similarly affected, but to a decidedly less degree than that of the hands.

Let me say, in passing, that the poisonous action of tincture of arnica upon the skin is not generally appreciated. Dr. White, of Boston, was the first to publish an account of three cases in which this accident occurred (*Boston Med. and Surg. Journ.*, No. 3, Jan. 21, 1875, page 61), and Dr. C. W. Earle, of this city, has added an account of one interesting case. This is the second which has been presented at this clinic, a patient similarly affected having been shown to the class last year.

Here, finally, are two young men who come in together, and who tell us that they have been engaged at the same time upon the same kind of work. They were employed by some master-workman to put a certain species of coloring material upon the interior walls of a house, using for that purpose the broad brush of the "white-washer." In this way, they tell us that their hands chiefly, and, to a lesser degree, also, their faces, were spattered with the coloring solution, and soon after this accident the eruption appeared. As they sit together, side by side, you see that the four hands are affected, each to nearly the same extent. You notice also that the resulting lesions of the skin are somewhat similar to those we observed in the case of the laundress, and that the disease is the same, though rather more pronounced. The palms are spared. The backs of the hands, and, to a less extent, the wrists and the lower part of the exposed forearms, display light- and dark-reddish, very irregularly outlined and slightly thickened patches of disease, with interspersed vesico-pustules, papules, and delicate crusts. Equally ill-determined islets of sound skin are here and there interposed. The interdigital spaces are to a less degree involved. They complain of considerable itching. Notice particularly that in each man the right hand is more involved than the left, and that the disease is decidedly aggravated in the region of the thumb, the adjacent forefinger, and the intervening web. Each of these patients informs us that he is right-handed. Observe, also, that one of them has employed a flax-seed poultice over a portion of the hand, and that the diseased skin to which this application has been made is sodden, unnaturally white, and is also the seat of a few superficial erosions. In one place, a rather painful fissure has occurred, where the integument has been in this way weakened, and in its weakened condition put upon the stretch.

Let us now endeavor to understand the lessons which this series of diseased hands can teach us.

In the first place, with respect to the etiology of these affections, we observe that in one instance syphilis is accountable for the lesions; and that in all the others we have a satisfactory explanation in the operation of external agencies. And yet, when we study the hands of our syphilitic patient, we see that the systemic disorder is not alone accountable for the local distress. Here, none the less, we find that the constant handling of the wet hose used by firemen has greatly aggravated, and thus prolonged, the palmar affection. This lesson is so useful and important, that no one can safely ignore it. By the hand, more than by any other portion of his body, man comes in contact with the external world in his daily toil. What wonder, then, that it displays in the highest degree, the resentments which all such traumatic, poisonous, and other injurious contacts arouse! Here we have an epitome of the entire etiology of eczema. Did you ever think of it, the hands of an infant at the breast, hands unused in toil, are much less frequently affected with eczema and dermatitis, than those portions of its tender skin with which the hands of its mother or nurse have reason to be most intimate? Its scalp, irritated by an effort to remove the incrusted *vernix caseosa*, its buttocks covered by soiled napkins, and the neck, with which its clothing frequently comes into harsh contact, are in its case much more commonly involved. And if we go a step further, back to its uneventful life *in utero*, we discover that then it is absolutely and always saved from every accident which can endanger an eczema or dermatitis, as it floats in its warm water-bath, protected by its natural unguent from the macerative action of the surrounding fluid. If we are told that these disorders are due to a diathesis—rheumic, arthritic, dartrous; if we are bidden to refer these maladies to preverted innervation, to assimilative debility, or to other equally indefinite causes, let us remember these striking facts. No child ever came into the world eczematous.

Notice, if you please, also, that in each case, our patients being all confessedly right-handed, that in each the right hand is most seriously involved, and that part also of the right hand which is most efficient in ordinary handicraft, namely, the thumb and index and the neighboring parts. How can any one whose patient exhibits these striking symptoms conceive for a moment that the skin disorder is one which originates from "impurities in the blood." If we go a step further, and inquire respecting the invasion of the palms in one class of cases and their immunity in another, we can receive an approximate answer only. Doubtless the reason why the backs of the hands are involved and the palms spared in the eczematous subject, is that the latter are relatively much thicker, and as a result much more fitted to resist the action of external irritants. Supposing that the latter exert an equal influence upon both planes of the hands, the dorsal surfaces naturally suffer first, because they are the more delicate in texture. That this is so, we are the more persuaded, because we do find very remarkable instances in which the palms alone are involved in eczema; cases, I should add, in which usually the parts chiefly affected have been long subjected to the action of a severe caustic or other irritant. In these rare instances

the surface is commonly symmetrically and diffusedly involved, being abnormally reddened or even whitened, in consequence of the thickening of the epidermis, the resulting inextensibility often producing a species of semiflexion of the fingers toward the palm, and a proportionate difficulty in their complete extension.

If we next inquire why the palms alone are involved in the syphilitic patient, we are at a loss for a satisfactory explanation. Still, the very selection of a particular portion of the general surface of the body is a striking characteristic of many of the late syphilitic eruptions, and of not a few of those which may be regarded as early. The palmar and plantar syphilodermata occur both as early and late manifestations of the malady. This that you have seen is the late form, as we know, not merely by comparing the lesions with the date given in the patient's history, but also by inspection of the palms. The large size of the disks; the exfoliating lamellæ of epidermis, which have probably been chiefly responsible for the grave misnomer of "syphilitic psoriasis," applied to the disorder; and the deep fissures in an ulcerated condition which have formed centrally—those are not very like the more superficial, pea-sized, and merely desquamative lesions seen often within a few months after infection. To repeat, many of the late lesions of the disease are conspicuous for the selection of a special area: some linger near the nose; others at the anus; others, again, over the tibiæ, the olecranon, or the patella.

Usually with a palmar syphiloderm we can discover a corroborative lesion in the mouth, the glands, or on some other portion of the body. Although there has been some doubt expressed upon this point, I am confident that cases occur where, after careful scrutiny, the hands alone are found to betray the evidence of syphilis in its objective symptoms. Pathologically, we know that the exfoliation and fissuring of the epidermis are accidents of the process. The disease really involves the derma, and it is only because the derma in this situation is covered by so dense an outer envelope that the phenomena are presented to us in this form, In the face, where the sebaceous glands are numerous. products of the syphilitic process may have a seborrhœic character; about the anus, where there is greater heat and moisture, vegetations often form; on the palms, dry, unprovided with sebaceous glands, and horny, naturally the thick epidermis plays a prominent part in the symptoms.

This much understood, the diagnosis and etiology of the several diseases of the hands are readily reached. Syphilis aside, there are few disorders limited to these organs which are not either forms of dermatitis or eczema, including under the latter term the eczematous lesions seen in scabies, a disease with an etiological difference. In the latter, we look to see a great multiformity of lesions, and, radiating from some of the pustules or vesicles, the little furrow or canaliculus where the female *acarus* has tunnelled her way beneath the skin and there deposited her ova. Scabies is rare in this city, and has been equally so in many of the Eastern towns of our country since the late civil war came to an end. But the increasing tide of immigration is, at last, restoring to our clinics a disorder familiar, indeed, to our fathers in medicine, but which was fast becoming to us a curiosity. You will be surprised to notice how many of the diminutive news-sheets published in this country during the early part of this century contain advertisements of remedies to cure "the itch."

Lupus erythematosus is occasionally seen upon the hands. I showed a young lady to the class, a few months ago, with a characteristic patch of the disease upon one hand; and the late Dr. Fox, of London, in his plates, gives an illustration of the affection as it occurs upon the same organ. It decidedly prefers the dorsum of the hands, and spreads here rather more actively than upon the face, doubtless in consequence of the freer movements and accidents of contact of these organs. It is for precisely that reason, I suspect, that it tends to run up to and encircle the thumb, often spreading at one border while it leaves at the other its characteristic scar, the most elegant of all cutaneous scars. This is smooth, uniform, unattached and punctate, suggesting the action of the engraver's tool in what they term the "stippling" process. By many of its characteristic symptoms you can here recognize it: Its attached scales, often worn off from the hand, it is true; its deeper than light-reddish shades; and its frequently roughened, well-nigh ichthyotic aspect, when it has occurred on the hand of the seamstress. But I beg you to remember in particular one tolerably constant diagnostic symptom of value: the patch of erythematous lupus on the hand, however it may differ in other respects from those upon the face, acknowledges its relation to the latter in its distinct outline. Only the palmar disk of our syphilitic patient had such a contour. All the other hands, whether affected with a dermatitis or an eczema, were singularly free from this distinctness of contour in their patches of disease. It is, in general, safe to say, never hastily decide that patch of cutaneous disease to be eczematous, where you can take a pen or pencil and distinctly outline the involved area at every point. Lastly, erythematous lupus usually involves one hand only.

There are a few other disorders found upon the hands which could scarcely be confounded with those we have here seen. In lichen ruber planus, the groups of glazed and umbilicated papules, found at the wrist chiefly, are the symptoms of a disorder rarely seen in this country. In herpes iris, or erythema multiforme, by whatever name you choose to call it, the mere fact of the concentric and regular arrangement of circlets of vesicles of different ages in a single patch, upon the back of the hand chiefly, would suggest the existence of a special disorder. This, though less rare than the affection last named, you will occasionally encounter. It is but a few weeks, since I was shown an exquisite example of this disorder upon the hands of a young woman, the patient of one of my colleagues.

Then there are those isolated, but often closely agglomerated, vesicles, or vesico-pustules, and even bullæ, excessively painful and often surrounded by an inflammatory halo, which are seen upon the lateral surfaces of the fingers, and, indeed, upon all parts of the hands, in those cachectic patients who have been sweating profusely. Fox, and Hutchinson, of London, and others, have given these lesions different names, "dysidrosis," "cheiro-pompholyx," etc., but their exact pathological history is not well understood.

The hands, too, especially on their dorsal surfaces, often exhibit patches of vitiligo. In such case the lesions are readily recognized by the entire absence in them of hyperæmic and exudative symptoms, and the manifest limitation of the anomaly, to the mode in which the pigment is distributed. The coloring matters of the skin are then merely absent in tolerably well-defined areas, and heaped up, as it were, about the borders of the decolorized disks, in chocolate to fawn-colored shades. Occasionally a species of irregular reticulum can be discovered over the backs, usually of both, of the hands, composed of blanched spaces surrounded by an irregular mesh of pigmented striæ, the distinction thus presented to the eye being, in such cases, much more obvious during seasons of hot weather. At such times the effused sweat seems to be in part effective in what may be figuratively described as a sweeping away of the pigment material from certain definite whorls, around which it is accumulated in excess.

Lastly, we should not forget the frequent occurrence, in early life, of simple warts upon the hands; in middle life, when the patient is toiling in manual labor, of resulting palmar callosities, malignant pustules, dissecting wounds and erysipelas of the same organs; and, in advanced years, of the epitheliomata, which may occur usually upon the dorsum of one hand only, whose origin here can be frequently traced to an irritated wart or similar hypertrophy.

Let us note before we dismiss the subject, that the hands are commonly spared by psoriasis, whose plaques, however, in rare instances can be recognized upon the dorsal surfaces. Their occurrence upon the palms may be regarded as a pathological curiosity, and upon the palms only, as an expression of the disease to be received with great doubt and reserve. Tinea versicolor is never seen on the hands, though the other vegetable parasites may flourish there, and even involve the nails. These organs also are affected in many diseases involving other regions of the skin, as in lepra, pityriasis rubra, multiple sarcoma, and the exanthemata. In smallpox the pustular lesions are here, as a rule, much less numerous and well-developed than upon the face, and the resulting cicatrices are proportionately fewer and inconspicuous, often entirely absent when the face is deeply scarred.

Now the treatment of the hands, we have seen, is a very simple matter. Our syphilitic patient alone will receive internal treatment, the biniodide of mercury in union with the iodide of potassium, which we are accustomed to employ in the combination known as the *sirop de gibert*. His hands will be macerated at night in very hot water, and then well anointed with equal parts of Squibb's six per cent. mercurial oleate and vaseline, retained, during the night, in contact with the skin by drawing over the hands a pair of undyed leather gloves. All the other hands will get well if the cause of the disease in each be removed, and the organs are given sufficient rest. This is a matter of some importance. Never permit yourself to be pushed by a patient into the false position of attempting to "cure" the disease of his hands, with your drugs for the stomach and salves for the skin, while the sufferer is aggravating the trouble in the daytime by the accidents of his daily toil. If for the poor hard-worked seamstress, and the poor father of a large family, the latter is imperative, you can sympathize with their necessities, and aid them greatly, while you give them to understand that your method of treatment is not the best and most effective, but vastly inferior to another. In other words, tell them the whole truth, that the organs will take care of themselves if simply protected and disused.

The first thing to do under such circumstances is, for those which are acutely inflamed, to soak them well every night in a weak solution of borax or the bicarbonate of sodium, in water just as hot as can be comfortably tolerated, the hands being immersed for from ten to twenty minutes. This is usually grateful, alleviates the itching, and is not followed by the sharp reaction of cold water. Then they may be well smeared with a lotion composed of equal parts of olive oil and lime water, to which has been added a drachm of the bismuth subnitrate, and, when the itching is severe, also a drachm of dilute hydrocyanic acid. This makes a creamy preparation, usually well tolerated by the skin, which can be applied on soft bits of old muslin covered, if need be, with oiled silk or the Lister protective, to prevent evaporation. As the acuteness of the disease subsides, under the topical treatment, you may either protect their hands by the dusting powders, and for the financially impoverished, a package of "Oswego Gloss Starch" from the nearest grocer answers well; or you may select one of the many ointments useful in eczema, such as calomel, bismuth, zinc oxide, or litharge, incorporated with vaseline or cold cream. Only in chronic forms of the disease of the hands will it be proper to use such stimulating topical medicaments as those compounded of tar, resorcine, gynocardic acid, and naphthol.

One of our patients was decidedly worse in consequence of having applied a poultice to the hand. The use of poultices in diseases of the skin is much more limited than in surgical and medical practice. They are properly limited to the cases where crusts or other pathological deposits are to be softened before removal, and to cases where the skin is to be softened before exit is given to pus, either within or below its tissues, as in furunculosis and carbuncle. For disorders of the skin proper, such as eczema, dermatitis venenata and medicamentosa, and similar affections, the weakening of the skin by the action of a poultice is in general to be deprecated.

But we must not lose sight of the fact we had in view, before discussing any method of treatment. Protect these hands in a state of disuse, and they will all speedily improve, even those of the syphilitic patient; while the others will finally exhibit a complete involution of their several diseases.

ORIGINAL ARTICLES.

ON THE USE OF THE ACTUAL CAUTERY (THE THERMO-CAUTERY OF PAQUELIN) IN THE TREATMENT OF CARBUNCLE.

BY P. S. CONNER, M.D.,
PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE MEDICAL COLLEGE OF OHIO, ETC.

CONSIDERING the length of time that it has been recognized as a special surgical affection, the unmistakable character of its symptoms, and the numerous investigations that it has been the subject of, it is remarkable how diverse are the opinions, even to-day, held respecting the cause, the anatomical seat, and the safest and best treatment of carbuncle. Is it constitutional or local; does it depend upon injury, the entrance from without of micro-organisms, or the presence of morbid or irritant materials circulating in the blood; is it an evidence of, and consequent upon, diabetes; or may a condition of glycosuria be produced by it, to disappear before or at the time of its healing; is it the result of, or how far is it affected by, weather changes, mental disturbances, high living, or overwork and privation?

Is it primarily a dermatitis or a cellulitis; does it start in the sebaceous follicles, in the sweat glands, in the ordinary subdermal connective tissues, or in the *columnæ adiposæ* of Warren?

Interesting questions, all, but not to be considered at present. As respects treatment, there is as little unanimity of opinion. Shall reliance be had upon the internal administration of drugs; and, if so, shall they be tonics and stimulants, or supposed special eliminants, or recognized parasiticides, as iodine and the bichloride of mercury? If any local treatment is employed, shall it be simple poulticing or hot-water dressing, or stimulating appplications, as turpentine or blisters; or shall incisions be made, that tension may be relieved and the separation of sloughs facilitated; or shall the whole tumor be cut away; or shall the cautery, actual or potential, be early and thoroughly applied?

That many of the less severe cases will, without much trouble, get well under simple treatment, every one knows; and at times even the more threatening ones will eventuate well. The largest carbuncle that I have ever seen, occupying the posterior half of the left thigh in its lower two-thirds, was recovered from in about five weeks, and with very little resulting impairment of the functional integrity of the limb, under the application of mixed castor-oil and turpentine. The long-time standard treatment by incisions, transverse or crucial, is known to occasion at times severe, even dangerous bleeding; and very often neither relieves the pain, arrests the spread of the inflammation, nor, by facilitating the separation of the sloughs, hastens the recovery. Subcutaneous incision is followed by no better result in many cases. The application of caustics (Vienna paste, chloride of zinc, etc.), which has been with some, particularly the French, surgeons a favorite, is objectionable on account of the pain that is caused, the excessive suppuration which may follow, and the considerable loss of substance which is often produced. The use of the actual cautery is not new; but only within a few years, since the introduction of the Paquelin instrument, have we had a convenient way of using high heat without the unpleasant accompaniments, not to say annoyances, of the old-time cautery irons.

As the result of my own observation, limited, it is true, but still sufficient from which to draw some conclusions, I am satisfied that by the early application of the thermo-cautery knife, or, much better, the hammer-head (if I may so term it, the *foyer en forme de champignon*, of Collin), the pain may be quickly, generally almost at once, relieved, and the progress of the inflammation arrested. The reported observations of others, as those of Verneuil and of Post, confirm me in my opinion. In the cases that I have treated in this way little or no suppuration has occurred, and the eschar has separated in due time, leaving a healthy granulating surface that has soon cicatrized. Even when the carbuncle has been fully formed, and pus has begun to discharge through the skin-openings, I have derived, I believe, much positive benefit from the thorough application of the cautery, thrust into and through the dead tissue; materially lessening the suppuration, stopping the extension of the disease, hastening repair, and securing a scar-deformity decidedly less than that after any other method of treatment.

Either a white-heat or a dull red may be employed; the use of the latter, of course, being much less likely to be attended with bleeding. In my own cases no troublesome hemorrhage has been produced by the application of the highly-heated cautery. The after-treatment has been very simple, either dry cotton or hot-water dressings being applied until after the separation of the eschar or the slough.

As every one will admit, the special danger in the severer cases of carbuncle lies either in the exhaustion consequent upon protracted suppuration occurring in an individual already debilitated, or the subject of grave organic disease, especially of the kidney; or, as is more usual, in the great liability to the development of one or other form of blood-poisoning. There must, therefore, be great advantage in a method of treatment which will promote early separation of the dead tissue, will restrict the suppuration within comparatively narrow limits, and will—as Langenbeck has stated—best secure firm clots and prevent pyæmic accidents. Without presuming to go as far as Vallette has done, in declaring that for carbuncle the actual cautery is "an unfailing specific, more infallible than quinia in the treatment of intermittent fever;" and fully believing with Trelat, that "every exclusive method is bad in so far as it is exclusive," and that "the treatment must vary according to the progress and form of the swelling, and also according to the general condition of the patient;" I cannot but think that in other than the milder cases the use of the thermo-cautery will yield better results, as respects time, suffering, and local damage, than any other method of treatment, therapeutic or operative. As in the first day or two it is often impossible to determine whether the carbuncle is or is not going to run a mild course, as cauterization may abort the disease, and as it is a procedure not specially severe, and not in and of itself dangerous, one certainly would be justified in its early adoption in any case.

EXCISION OF ULNA FOR OSTEOMYELITIS, CONSECUTIVE TO AMPUTATION FOR GUNSHOT WOUND.

BY WILLIAM A. BYRD, M.D.,
OF QUINCY, ILLINOIS.

OSTEOMYELITIS of a violent type is one of the most unfortunate circumstances that may complicate the progress of a case after amputation. Many lives have been sacrificed by temporizing; the surgeon hoping that the bone may necrose completely and be thrown off, instead of amputating above the next joint. It would be useless for me to go into the consideration of this matter upon this occasion, and any one interested in the subject will find it very ably elucidated by Prof. Chas. MacNamara in his *Lectures on Diseases of the Bones and Joints*, 2d ed. I take it that Prof. John Ashhurst, Jr., agrees in the main with Mr. MacNamara, from the statement he makes regarding this condition in his article upon amputation in the *International Encyclopædia of Surgery*, vol. I. pp. 604, 605. Other authors that I have consulted do not seem to be as well settled in their convictions, as the matter is written about very indefinitely.

When acute osteomyelitis sets in after an amputation of the forearm, a proper conservatism would require that an exsection should be performed, taking away the whole of the diseased bone, which is the focus of infection. That the radius should be so treated I suppose none would gainsay; but the possibility of having a stiff enough articulation between the ends of the radius and humerus, or there being no reproduction of bone from the ulnar periosteum, so as to procure an artificial joint, therefore allowing the end of radius to hang off loose from the end of the humerus, like the end-

stick of a flail, might deter some surgeons from making an excision of the ulna. But should such an untoward result ensue, the radius could be removed at the elbow-joint, after a sufficient time had elapsed to prove that it would remain useless; or, possibly, be in the way. Such an operation would be one of comparatively little danger, as only soft tissues would be involved in the incision, and the patient would receive the benefit of the doubt.

The following case will illustrate my meaning: October 18, 1881, George Mullican, a robust countryman, aged 26, while out hunting discharged one barrel of his gun while dragging it after him in the brush. The charge of duckshot passed through the left wrist and lower arm, leaving the hand attached to the arm by only a few mangled tendons, and an anterior and posterior strip of skin. He walked some four miles to a railroad station, and came to the city on the first train, having tied a handkerchief above the wound to prevent hemorrhage. I saw him about four hours after the receipt of the injury, and amputated the arm, with the assistance of Dr. Geo. W. Connell, at St. Mary's Hospital, at the junction of the lower and middle thirds. The arteries were twisted and the flaps brought together with catgut sutures. The wound healed almost entirely by first intention, there being a very small spot at one corner that granulated. He progressed so nicely that I let him go home, ten miles in the country, on the 31st of the month. I met him almost every day for awhile, as he would come into the city in the morning and return home in the evening.

The night of November 21st he went to a dance, and remained up nearly the whole night. The next morning, feeling very badly, he concluded to come into the city and see me. He went to the railroad switch, where there was no depot, but where the trains stopped for passengers. The day was very cold and rainy, and the train was an hour and a half behind time, so by the time the train arrived he was thoroughly wet and chilled. When he got to my house he had a high fever, and the arm was quite painful. He was sent to St. Mary's Hospital. When I called to see him in the evening the right lung was hepatized, and he was raising rusty-colored sputa with the cough he had. Rigors ensued, with copious sweatings. The stump became greatly swollen and suppurated freely. Shreds of connective tissue came away, and the cicatrix at the end of the stump gave away, leaving the ends of the radius and ulna exposed. The ulna was discolored, eroded; and the discharges from it were quite offensive. A sinus opened just to the inner side of the coronoid process. Appetite was gone, tongue was dry, and there was a pinched appearance of the face, with occasional delirium. Having just completed the reading of Mr. MacNamara's most excellent book, I lost no time in putting his advice to the test. November 29th, after carefully examining both bones, and finding the radius perfectly sound, I decided upon removing the whole of the ulna, which was done with the efficient aid of Dr. G. W. Connell. The bone was so eroded that it was almost divided, and had lost at least half its original weight. All this destruction of bone in one week!

The delirium left him immediately after the operation; the dulness of the lung gradually passed away; but the rigors still continued, though much less severe than before. There remained hepatic enlargement and pain, with a continuation of the sweating. Thinking that I detected deep fluctuation in the liver, just at the lower edge of the ribs, I passed an aspirator needle three inches deep into its substance, at about the outer end of the eleventh rib, December 7th, when about a drachm of seropurulent fluid was obtained—nothing more. The next day his side was free of pain, and after this the hepatic enlargement gradually disappeared without further pain.

December 24th he left the hospital, still having some night-sweats, and greatly reduced in flesh. The wound in the arm was healed, and the joint stiff. My advice was to move the joint as much as possible, as soon as the tenderness would permit. He gradually recovered his health, and the joint became more and more useful. There does not seem to be any reproduction of the ulna, but in its place there is fibrous tissue that answers the place of the bone very well. This tissue may eventually

Diagram showing the extent of flexion and extension possessed by the arm.

ossify. He can hold a fork in the flexure of his elbow when carving his food; uses the radius to hold his lines when driving horses; and, in fact, finds the arm very much more useful than it would have been had it been amputated above the condyles of the humerus, or even at the joint. The accompanying figure, from a photograph taken a few days since, shows the result of the operation.

THE REDUCTION OF CANE-SUGAR BY HYDROCHLORIC ACID AND BY GASTRIC JUICE.

BY A. M. BLEILE, M.D.,
LECTURER ON PHYSIOLOGY, STARLING MEDICAL COLLEGE, COLUMBUS, OHIO.

WHILE conducting a series of experiments having for their object the behavior of intestinal juice, *i. e.*,

glycerine extract of intestinal mucous membrane, in fluids of various reactions, I noticed that in all cases where HCl was used there was a decided action on cane-sugar. Even in juices, which were almost inert as regards cane-sugar in neutral or alkaline solutions, I always had a decided grape-sugar reaction in fluids acidified with HCl, and the greater the acidity the better marked was the reaction. The reducing sugar resulting from the digestion of cane-sugar is called grape-sugar mainly because it reduces copper salts in alkaline solutions.

From later researches carried on by a number of authors it is somewhat doubtful whether the sugar formed in digestion from starchy matters or cane-sugar, is grape-sugar or another sugar corresponding with the former merely in several of its reactions. Indeed, Claude Bernard, who first pointed out the power of intestinal juice to convert cane-sugar, stated that the resulting substance was a mixture of dextrose or grape-sugar and levulose. The term grape-sugar is therefore used provisionally only in this paper. This constant production of grape-sugar in acid solutions of course led to the proposition that HCl was the active agent.

It is well known that a solution of several per cent. HCl will reduce cane-sugar at the boiling temperature, but as to its effect in much greater dilution, and at a lower temperature (40° Cent.), I could find no statements in the literature at my command, and hence proceeded to investigate for myself, the process being in brief as follows: Cane-sugar solution was added to HCl, of such concentration that the quantity of sugar solution added would bring out the desired per cent. of acid in the resulting mixture. .5 gr. of cane-sugar in 20 c.c. of mixture was the usual proportion, being equal to 2.5 per cent. of cane-sugar, or 2.62+ per cent. of grape-sugar in case it should all be converted into this substance. The per cent. of HCl in the different mixtures was varied as stated in the table below. Tubes charged with such solutions were then placed in the digestor, kept at a temperature of 40°–41° Cent., and their contents examined at given times, as seen in the table.

Percentage of Grape Sugar Found.

HCl per cent.	.15 per cent.		.2 per cent.		.3 per cent.		.5 per cent.		.6 per cent.		.75 per cent.		
	Acid. .35	Juice. .31	Acid. .67	Juice. .67	Acid. 1 11	Juice. 1.15	Acid. 2.08	Juice. 2.06	Acid.	Juice.	Acid. 2.38	Juice. 2.38	1 hour.
Sugar in per cent.	.73	.86	1.43	1.50	1.67	1.72	2.18	2.25	2.41	2.46	2 44	2.50	3 hours. Time.
	1.07	1.11	1.79	1.73	2.22	2.18	2.44	2.44	2.44	2.50	2.60	2.60	5 hours.

The quantitative analyses were made by Prof. C. C. Howard with painstaking accuracy, and can be thoroughly relied upon. The Fehling method was the one used for these determinations.

HCl in even greater dilution than any indicated in the table will reduce cane-sugar under the same conditions. As shown by simply qualitative tests so little as .005 per cent. of HCl will give an appreciable quantity of grape sugar in about two hours.

Seeing from these experiments with what facility cane-sugar is reduced at the body temperature by very dilute acid, it suggested itself that the gastric juice, containing as it does free HCl, would have a similar effect unless indeed its pepsin or some other constituent would materially alter the process.

Another set of experiments was made, comparing pure acid solutions with artificial gastric juice (glycerine extract of stomach) of the same titre. From these it appears that the pepsin has no effect whatever, the quantities of grape sugar obtained in parallel cases being sufficiently close to be accounted for by the unavoidable errors of analysis.

Natural gastric juice, as obtained from the dog through a gastric fistula, has a speedy reducing action on cane-sugar, as I have already stated in a paper read before the Ohio State Medical Society. The inference is that the action here as in the artificial juice is due to the free acid. Certainly, the more marked the acidity, the more speedily is the grape-sugar to be found. Occasionally a juice is obtained very slightly acid, especially after the animal has been used for several days in succession and the stomach considerably irritated, which does not reduce cane-sugar, nor does it however have any action on fibrin. The mucus which sometimes flows from the fistula in abundance at the beginning, and which is said to slowly reduce cane-sugar (Foster), can be easily separated from the pure juice by filtration.

Quantitative experiments, whether it is the acid in the natural juice, too, to which the reduction must be ascribed, and whether any modifying influences come into play here, are now in progress and will be communicated in due time.

I am led to make this preliminary statement from the fact that Leube (*Virch. Arch.*) has recently, but after the preparation of my paper referred to above, announced that the human gastric juice also reduces cane-sugar.

The commercial cane-sugar I find is totally unfit for these experiments, as all obtainable samples already contain a notable quantity of grape-sugar; crystalized sugar in the shape of rock candy, however, can readily be obtained free from such admixture.

REMITTENT FEVER IN THE SOUTH.

BY FAIRFAX IRWIN, M.D.,
PASSED ASSISTANT SURGEON, UNITED STATES MARINE-HOSPITAL SERVICE.

REMITTENT fever, or as it is popularly called on the Cape Fear, "river fever," is so common, and aside from its dangerous character, so expensive to ship-masters and owners that a few remarks on its character and treatment will not seem out of place, especially at this its chosen season. This article is based on the results obtained from the treatment of ninety cases of remittent fever during the past

eighteen months, all of which have recovered with an average duration of treatment of about nine days per man.

These cases were all treated in the Marine Hospital in Wilmington, N. C., and were, as a result, in a very favorable situation for observation. To the treatment, followed with little variation in all cases, the favorable result is attributed. That too much is not claimed will be readily allowed by any who are acquainted with the character of the malarial fever in this region, and especially when it is remembered that this disease is clinically the same as the bilious fever of thirty or forty years ago, which was itself so fatal.

The river fever is seen but in isolated cases before August, and from that time increases in virulence until the kindly hand of frost is laid upon it.

The most severe cases are seen among the sailors, especially those unacclimated, and is directly traceable to exposure at night to the poisonous exhalations from the rice fields along the river. The sailors sleeping upon the vessel-decks on warm nights are soon attacked, while the captains sleeping ashore usually escape entirely. Seamen from foreign vessels fall an easy prey, and give the largest percentage of malignant cases.

It is not to be forgotten, however, that sailors in addition to exposure are usually filthy in their habits, reckless and dissipated to a degree. Before passing to a short sketch of the natural history of this fever, it may be well to refer to a common idea held by seafaring men, that salt water "brings out the fever," a vessel after remaining for ten days or two weeks in the Cape Fear River usually drops down to Smithville at its mouth, to complete loading, and here frequently, after having been healthy all of the time spent above, the crew succumb almost suddenly to fever, hence the notion of salt water "driving it out." I believe this is nothing more than a coincidence, the outbreak of the disease after its regular period of incubation. Sailors have died at sea after leaving Wilmington, of the fever, though healthy on departure and with such malignant symptoms as to cause masters to report them as cases of yellow fever.

Remittent fever as I have seen it here, after an incubation of from ten days to two weeks breaks out quite suddenly and with alarming symptoms from the first. Perhaps in some cases a certain lassitude and weakness for a few days may precede, but as a rule the onset is sudden.

Contrary to the statement in most works on the subject, there is no initial chill; this did not occur in any of the ninety cases treated. Many men were brought into the hospital insensible, having been taken sick during the day.

The prominent symptoms were a dull, stolid countenance; weary, slouching gait; acute lancinating pains in the head and back, dull pains in the limbs, tenderness on pressure over the region of the stomach with great irritability of that organ; a characteristic tongue, large, flabby, showing indentations of the teeth, and thickly coated with bluish-white fur, rarely dry except in protracted cases, and often so large as apparently to fill the mouth. The coating was often absent, but the bluish-white tint was invariably present.

The full rapid pulse, throbbing carotids, and moist surface showed the excited circulation. The sweats were in most cases as copious and as debilitating as in phthisis. The temperature ranged from 100° to 105° (38° to 40.4° C.) on the first evening, the average being 104° (40° C.)

There was a marked tendency to congestion of various organs, especially the lungs, but an implication of the liver to any appreciable extent was not observed; the yellow hue of the skin so often spoken of in books was not seen. Albumen was not discovered in the urine in any case. Delirium was rarely present, severe cases were more apt to become comatose. The irritation of the stomach was frequently most severe and difficult to manage, everything being rejected and passing on to the vomiting of pure bile. There was no eruption.

There is little danger of a mistake in diagnosis: the season of the year, the sudden seizure, the steel-colored tongue, acute pains in the head and back, and distinctly remittent range of temperature are characteristic.

There was rarely more than one exacerbation, owing, it is believed, to the large doses of quinia used. When a second exacerbation followed, it was always found to be due to an insufficient use of quinia. In the whole number of cases treated there was little variation of symptoms, but a few interesting exceptions may be mentioned.

Epistaxis was somewhat common and one case required plugging of the nares to prevent exhaustion from loss of blood. Hemorrhages from the bowels was present in a case which lasted two weeks; there were no other symptoms of typhoid fever, however. One case so strongly simulated cerebro-spinal fever as to leave the diagnosis in doubt for a few days; there was well marked opisthotonos, but recovery followed in due course.

A case in private practice seen in consultation with Dr. Geo. G. Thomas, of Wilmington, had the Cheyne-Stokes' breathing perfectly, and presented the appearance of approaching dissolution. Large doses of quinia were being given but the disease had advanced so far before advice was asked for that it seemed as if the nervous system would be overwhelmed by the poison before the remedy had time to act. A blister was applied to the back of the neck and atropia sulphate (0.0010 gramme) given every three hours, with good effect, and recovery followed. Atropia was given to counteract the slow spasmodic breathing; the *besoin de respirer* being almost absent, as in opium poisoning.

The *treatment* used in the ninety cases to which this paper chiefly refers was based on the principle that remittent fever is caused by a poison now known as malaria, which is present in almost overwhelming degree, and to which quinia is a direct antidote if used in large doses.

Cases showing the usual evening temperature of 40° C., and upward were given from 30 to 45 grains (2 to 3 grammes) of quinia sulphate, usually in solution with dilute sulphuric acid, and largely diluted with ice water. As the stomach in many cases was

so irritable as to reject this really nauseous dose, the quinia was then given in pills freshly made with glycerine; when these were rejected, as was often the case, the drug was administered hypodermically, the dose in this case being from 10 to 15 grains (0.666 to 1 gramme). The solution for hypodermic use was made with citric acid, and although many times used, no abscess ensued in any case.

This large dose almost invariably reduced the temperature from one to three degrees by morning, the quinia was then given in doses of 5 grains (0.333 gramme) thrice daily, and the large dose again repeated at night if the temperature rose. This method, with a few exceptions, cut short the fever in from three to five days, as the average duration of nine days for the whole number of cases will show. Some, especially where there was an existing organic disease, were more rebellious, and required large quantities of quinia before convalescence was established.

As much as 465 grains (30 grammes) of quinia were given in eight days in two different cases, and no ill effects were observed; in fact in no case did quinia cause any disturbance beyond deafness which soon passed away under cessation of the drug and small doses of hydrobromic acid. Dimness of vision was never complained of.

If the bowels were inactive, an enema was given at once, but no preparatory treatment was ever used. As the skin and kidneys were active, opium or diaphoretics were not called for. To moderate the heart's action fluid extract of aconite-root in one drop doses every four hours was given in most all cases; this, with ice compresses to the head, was about all the treatment.

The irritable stomach was best controlled by creasote or vin. ipecac. (5 minims) 0.333 cc. every two or three hours.

Rigid milk diet was given and no stimulants used. It is desired to insist upon the needlessness of the almost universal custom of preparing the system for the action of quinia, much valuable time is lost in an unnecessary procedure and it is thought that opium is positively contraindicated by the symptoms.

In conclusion, the fact should not be lost sight of that remittent fever is eminently a disease to be prevented. While vessels are in the river, the crews should be required to sleep ashore. Captains should be furnished with clinical thermometers with instructions for their use, and on the first indication of fever, a dose of at least 30 grains (2 grammes) of quinia should be given.

The total number of cases observed during eighteen months was ninety, total number of days treatment four hundred and forty, average per patient nine and one-third days.

HOSPITAL NOTES.

VIENNA GENERAL HOSPITAL.

(Service of PROF. CARL BRAUN.)

CÆSAREAN SECTION WITH SUPRAVAGINAL AMPUTATION OF THE VAGINAL PORTION BY PORRO'S METHOD.

(Specially reported for THE MEDICAL NEWS.)

THE fall semester of the Vienna Medical School has commenced in all departments with unusual brilliancy. Upon the second day of the new term, October 17th, Prof. Carl Braun performed a Cæsarean section, Porro's method, before his class, upon the person of a dwarf.

The patient, a native of Austria, thirty-six years old, married, was received into the wards during September in her *eleventh pregnancy*. The history of the case, as collected from the records of the three obstetrical clinics of the General Hospital, is briefly as follows:

The members of patient's family, with exception of herself, were perfectly healthy; three sisters, who are now living in the country, are in a normal condition.

In 1866, the patient came to Vienna to live; in 1869 she became pregnant, and was delivered, in the eighth lunar month, of a child, which is living to-day; instrumental aid was required in this labor.

She married in 1871, and became pregnant in 1872; the second pregnancy resulted in an abortion in the sixth month, during convalescence from an attack of typhus. Since 1873 she has suffered more or less constantly from "gout" ("gicht"), and has aborted in each of her succeeding pregnancies, until the present one, before the sixth month.

The patient was a dwarf, of delicate frame, was unable to walk, and could not move her upper extremities without pain; she was greatly emaciated; the bones were soft, somewhat pliable, and very sensitive, although she did not present to view as high a degree of *osteo-malacia* as one frequently observes in Austria,

When lying flat upon her back she was comfortable. A remarkable degree of intelligence was evinced throughout her stay in the hospital.

She stated that her last menstruation occurred about January 25th. Examination by abdominal palpation confirmed her statement, revealing pregnancy in the ninth lunar month, head presentation; combined external and vaginal exploration revealed an osteomalacic pelvis possessing a high degree of asymmetrical contraction, constituting a "three-cornered pointed heart figure" (dreiwinkelig spitze herzfigur), classified by Braun under the category of "more rarely occurring contracted pelvis."

The right sacro-cotyloid diameter or microchord of Ritgen measured 4 cm.; the left microchord measured 3.5 cm.; the normal length of each microchord is 8 cm. The horizontal branches of the pubes were prolonged forwards into a beak-like process, and measured between their bases 3 cm.; the transverse diameter of the pelvic entrance, measured through the promontory, was between 9 and 10 cm. The *conjugata vera* measured 8.5 cm.

The patient was at once isolated, given special diet, and preparations were made for Cæsarean section.

About 6 o'clock P. M., October 17th, the bag of waters ruptured, and active labor pains speedily followed.

Prof. Braun was summoned, and three hours later, assisted by Drs. Massari, Felsenreich, and Pritzel, performed Porro's supravaginal amputation of the vaginal portion, with Müller's modification. An interval of 30 seconds elapsed between the primary incision into the uterus and the removal of child and placenta.

The child cried lustily upon emerging from the uterus, proved to be a male, with a weight of 2800 grammes, and a length of 49 cm. The child, when last heard from in the Foundling Hospital, much to its father's disgust, was in a very vigorous, thriving condition.

After the pedicle had been carefully ligated, beneath the chain of Billroth's écraseur, this instrument was removed and replaced by the same surgeon's ovariotomy clamp. The stump was then thoroughly cauterized with Paquelin's thermo-cautery and the ovariotomy clamp was removed. A second set of ligatures were applied through the first system, in such a manner as to secure an approximation of the peritoneum of the

pedicle, upon all sides, over its raw surface. The pedicle was about to be returned to the abdominal cavity, when bleeding was noticed. The stump was again compressed by the ovariotomy clamp, both sets of ligatures removed, and reapplied.

After waiting some time, and noticing no recurrence of the hemorrhage, the *toilette* of the peritoneum was quickly performed, the pedicle returned to the abdominal cavity, and the abdominal incision approximated by the usual deep sutures of the lead-plated silver wire, and superficial silk stitches.

The woman reacted after the operation fully, and very little evidence of shock was perceptible.

The first day, after the operation, passed without moment; temperature being 37° C.; upon the second day, the patient commenced to vomit, and temperature rose to 38° C.; upon the third day, morning temperature was 39° C., evening temperature, 37° C.; upon the fourth day, towards evening, the woman died, with temperature of 38.6° C., and with all the symptoms of acute septic peritonitis.

The *autopsy*, conducted next morning, by Prof. Kundrat, revealed the usual lesions of acute septic peritonitis. In the cul-de-sac of Douglas, two or three ounces of bloody pus were visible. The plexus pampiniformis venosus, upon the left side, was filled with thrombi, and distended to the size of a large thumb.

Upon the right side of the stump, several ligatures had become loose, and hemorrhage into the cul-de-sac of Douglas had evidently occurred from the right plexus pampiniformis venosus, giving origin, doubtless, to the septic peritonitis.

Prof. Braun, in his remarks to the class, in the light of the autopsy, stated very emphatically that he would never again treat the pedicle of a pregnant uterus by the intra-peritoneal method. He was equally positive in asserting that the pedicle of uteri, amputated on account of fibroid tumors, should be treated by extra-peritoneal fixation. Prof. Braun quoted his brother, Prof. Gustav Braun, as fully concurring with himself upon the subject. The latter lost a very promising case after the same operation, last spring, from secondary hemorrhage.

Prof. Carl Braun has performed Porro's operation nine times. In eight cases the pedicles was treated by the extra-peritoneal method, and five recoveries were recorded. These five cases are living now in Vienna, and are exhibited annually at the clinic. The ligatures in Prof. Braun's last case were of strong silk, prepared antiseptically, and were most carefully applied.

MEDICAL PROGRESS.

NEW OPERATION FOR SALIVARY FISTULA.—At a meeting of the Cincinnati Academy of Medicine held on October 30th, DR. J. L. KROUSE reported a case of salivary fistula, stating that it was of interest on account of the operation employed being different from that usually mentioned in text-books, and on account of its favorable result.

The patient, a girl of five years, four months ago injured herself by falling upon a sharp piece of wood, which entered her cheek. The greater part of the foreign body was removed at the time of injury; but subsequently several smaller pieces came away. The wound discharged all the time, and not seeming to get any better, the mother brought the patient to the clinic of the Medical College of Ohio. Here the speaker saw the patient for the first time. She presented on the left cheek, midway between the angle of the mouth and the concha of the ear, a linear cicatrix, vertical in direction, of 1½ inches in length. At the upper border of the same, there was a large vesicle filled with turbid fluid. This, the mother said, would burst every now and then, discharging the watery contents over the cheek. As long as there was a free outlet to the secretions, the patient complained of no disagreeable symptom; but when the opening closed, then pain as well as swelling of the parotid region supervened.

On August 4th, that is three months after the receipt of injury, he operated by passing a silver wire armed with two straight needles through the external opening into the buccal cavity. The free ends of the wire were then twisted in the mouth and the external wound closed.

The object of the wire was to maintain an opening between the injured duct and the buccal cavity; it was allowed to remain there until the external wound had closed.

On September 5th, thirty-two days after the operation, the wire was removed. The recovery was perfect. The last time that the patient was seen was on October 24th, seven weeks after removal of wire. At that time the wound was still closed.—*Cincinnati Lancet and Clinic*, November 18, 1882.

[This operation is essentially the same as that described by Richelot. See THE MEDICAL NEWS, Aug. 12, p. 180. The elastic ligature is to be preferred on account of its greater rapidity of action. The whole method is however not new, being described in the French classics as the method of Deguise.—ED.]

ADVERSE OPINIONS ON TRANSFUSION.—PROF. VERNEUIL recently objected to the operation as a dangerous one, from which he had never seen any ultimate good derived, while the advantages which are said to attend its employment are obtainable by the hypodermic injection of ether. Recently, also, at the German Congress at Eisenach, Prof. König, of Göttingen, observed (*Berliner klin. Woch.*, October 2) that formerly he was a warm advocate of transfusion, but that he has come lately, like the majority of living surgeons, to think little of it. He has only quite exceptionally, and perhaps never, seen a favorable result follow its use, while from the injection of ether good effects are sometimes obtained. He therefore warns us not again to fall into the former prevalent transfusion-deception (*Transfusionsschwindel*). Prof. Schede stated that he was of much the same way of thinking as König, and now resorted to transfusion much seldomer than formerly. —*Med. Times and Gaz.*, Nov. 11, 1882.

A NEW TREATMENT OF DIABETES.—ADAMKIEWICZ believes that protein, the fundamental substance of the organism, may be regarded as being composed of sugar and ammonia, less some elements of water and oxygen. Consequently, if one could fix the excess of sugar present in diabetics by means of ammonia, we would have a chemical physiological treatment.

In his first series of experiments made on healthy men at the Berlin Charité, he arrived at the following conclusions: The chlorhydrate of ammonium is not decomposed in the intestinal tube of healthy men. The greater part of the ammonia absorbed with the chlorhydrate, disappears in the healthy body and probably appears in the urine in the form of albumen. The chlorhydrate of ammonium acts in the healthy body in about the same way as the chloride of sodium: it dehydrates the tissues and favors the decomposition of albumen. The decomposition of albumen and the excretion of albumen do not advance in parallel lines.

In his second series of experiments made on diabetics, he found that the ammonia disappeared rapidly, and that this assimilation coincided with a disappearance of sugar, and in slight cases the excretion of sugar might be entirely suspended. When the sugar does not disappear, the ammonia absorbed into the

system of the diabetic neither increases the quantity of water or urea; while when the sugar is absent the excretion of water is greatly augmented, proving that part of the ammonia is transformed into urea, and as such eliminated.—*Rev. de Thérapeutique*, November 1, 1882.

THE RELATION OF CHOREA TO RHEUMATISM.—MR. EDWIN RICKARDS read a paper before the Section of Medicine at the last meeting of the British Medical Association, whose purport was to support the view that chorea is a functional disease of the brain. From observation of a large number of cases, of many of which he has records, he has been led to believe that chorea occurs exclusively in individuals of an excitable nervous temperament, and at a time of life when the mind is least stable; that it may arise solely from excessive nervousness, which is frequently brought to chorea-point by fright, or some condition calculated to produce nervous debility. The fact, that mental disturbance is a potential cause of chorea, is, to his mind, presumptive evidence that it is the constant cause. In three of his cases, choreic movements followed the occasion of excitement within twenty-four hours. Now, if organic changes were brought about in so short a time, it is reasonable to suppose that, in protracted cases, terminating fatally, constant grave structural alterations would be found. Such, however, in his experience, is not the case. The proposition, that chorea is caused by mental disturbance, is supported by the fact, that the movements are to a variable extent under the control of the will; and when the mind is at rest, as in sleep, cease. The shifting, too, of the movements, seems to contraindicate any fixed lesion. It might be urged, Why does not fright more frequently cause chorea? To this objection, he would reply, that an attack of chorea from fright is determined by the nature of the terrifying agent, and the mental constitution of the individual. A trivial incident may seriously impress a nervous child, while a child who is not of a nervous temperament might not be shocked by a far more formidable occurrence.

And, now, as to the connection between chorea and rheumatism. The causal relationship between these two diseases must, at present be purely speculative, as the etiology of rheumatism is as yet undetermined. He is inclined to think that we must look to the nervous system for the primary cause of that disease. It seems to him probable that functional nervous disorder may lead to blood changes, which give rise to the symptoms indicative of rheumatism; and, if this were so, we should have a common cause for the two diseases. He has been much impressed by observing what nervous temperaments rheumatic patients possess —how great is the nervous debility during and after an attack; it is out of all proportion to what might be accounted for by the pain they suffer, and the *regimen* they undergo. His experience, up to the present time, has led him to the conclusion, that valvular disease of the heart is associated with chorea only through rheumatism. Four, and only four, chorea cases have been admitted into the hospital under him without heart-disease, and discharged from it with damaged valves. In these four cases, the endocarditis was accompanied by well-marked symptoms of acute rheumatism. In no one instance has he seen valvulitis develop in a choretic patient unconnected with rheumatism.—*British Medical Journal*, November 11, 1882.

PRECAUTIONS TO BE TAKEN AS REGARDS TYPHOID FEVER.—The Hygienic Council of the French Académie de Médecine have drawn up the following instructions to be observed when the presence of typhoid fever is recognized.

1. *Isolation.*—The patient should be isolated as far as possible from the other inhabitants of the house; if complete isolation is not possible, the patient should be taken to a hospital. If the patient remains in his home, only those persons who minister to his wants should have access to his chamber, while all children should be rigidly excluded. Nurses should wash in carbolized water; one per cent.

2. *Aeration of the Chamber.*—A room should be selected which can be readily aired. The hangings, curtains, and carpets should be removed, and the bed placed in the centre of the room.

3. *Disinfection of the Evacuations.*—All the ejecta of the patient, before being thrown out, should be thoroughly disinfected with a solution of chloride of zinc, 20 per cent. The privies into which the evacuations are thrown should also be flushed with this solution.

4. *Disinfection of Clothing.*—All the patient's body and bed-clothing before being removed from the room should be plunged into a solution of carbolic acid, 5 per cent., and then immediately washed.

5. *Disinfection of the Room.*—After the death or cure of the patient, charcoal should be burnt in the room with sublimed sulphur, and the chamber should then be closed for twenty-four hours. The chamber should then be washed with carbolized water, and not re-occupied until it has been freely aired for at least a week.—*Gaz. Hebdomadaire*, November 3, 1882.

THE DIAGNOSIS OF SYPHILIDES.—The diagnosis of syphilides is not at all times an easy matter, and any contribution to the literature of the subject will always be acceptable. DR. MAURIAC, Physician to the Hôpital du Midi, the well-known hospital for venereal affections in the male, delivered a very interesting lecture on the subject which may be summarized as follows: In giving a description of the topography of syphilides, Dr. Mauriac observed that their distribution on the different regions of the body presents certain peculiarities which are not found in other affections of the skin. Erythematous syphilide is found principally on the trunk and flanks, on the inner parts of the limbs, and on the flexor more than on the exterior aspect. The papular form has its seat of predilection on the face, the alæ of the nose, and on the forehead at the roots of the hair, the upper part of the neck, the trunk, and on the limbs in all directions. The scaly forms, with all their varieties, invade principally the palms of the hands and the soles of the feet. Pustular syphilides, superficial or impetiginous, affect the scalp, the beard, and, in general, the regions covered with hair. Ecthyma and rupia attack by preference the limbs, principally the lower limbs. As for tubercular eruptions, they are disseminated all over the body. Thus, it may be seen that syphilitic eruptions may affect the entire cutaneous covering of the body. There are, however, some parts of it which would seem to form exceptions to this rule, such as, for instance, the clavicular and sternal regions, where simple and parasitic eruptions are so common. The same may be said of the back of the hand, and this remark is particularly applicable to the exanthemata. Papulo-squamous eruptions are never seen on the limbs on the extensor surface, at least systematically, as is the case with one of the most common and most typical of non-syphilitic eruptions, psoriasis. The natural orifices, the commissures of the lips, isthmus of the fauces, orifices of the nostrils, the vulva, and anus, are the seat of predilection of the earlier syphilitic eruptions, and, among others, mucous patches are there particularly noticed. The circular forms of simple erythema may be found on all parts of the body; whereas the same forms of erythemato-papulous syphilides affect

by preference the chin, the cheeks, forehead, the neighborhood of the anterior and internal parts of the limbs, and the buttocks. The syphilides appearing later and affecting the tissues deeply are generally situated on the nose, lips, scalp, the sternal and clavicular regions, the buttocks, and more frequently on the legs near the joints than on the thighs.—*Lancet*, November 11, 1882.

Trismus of Cerebral Origin.—Prof. Lépine reports the case of a woman who died of cerebral apoplexy, who as the sole convulsive symptom had persistent trismus from the onset to the termination of the disease. At the autopsy there was found a small hemorrhagic foyer in the gray matter of the insula and at the foot of the ascending frontal convolution. This is the point whose excitation in monkeys causes movements of the jaws.—*Rev. de Méd.*, October 15, 1882.

Case of Carcinoma of the Stomach with Progressive Anæmia.—The following case occurred under the care of Dr. Barlow, in University College Hospital, London: Eliza H., aged fifty, was admitted on August 4, 1880. She sought relief for vomiting and loss of flesh. There was no hereditary history of cancer. The patient had enjoyed fairly good health, except for occasional "bilious" attacks, till nine months previous to admission, when she first began to lose her appetite and suffer with sickness, especially after food. From this time till the present date she had rapidly got worse, and her friends had noticed the great wasting and peculiar sallowness of her complexion. She had not long since vomited black matter, and her stools she had noticed were at times black.

Condition of Patient when first seen.—Sallow, cachectic complexion; great emaciation; the skin lying in loose folds all over the body. Very marked anæmia shown by the lips, conjunctivæ, and finger-nails. The superficial veins were not unduly distended. She had fairly good teeth and could masticate her food well, and there was no difficulty in swallowing. Though troubled with frequent vomiting, she complained of no pain, nor was there any tenderness over the abdomen on palpation; but a small hard tumor about the size of a pigeon's egg could be felt between the umbilicus and ensiform cartilage. This tumor, which could be felt lying in front of the spine, with its long axis transverse, did not pulsate, and only caused slight pain on pressure. The lower border of the liver could not be felt, and there was an intestinal note obtained on percussion over the lower two inches of the hepatic region in the nipple line. The spleen was not enlarged. The lungs were fairly healthy, nor was there anything noticeable with the circulatory system beyond feeble heart-sounds with reduplication of the first, and a small, compressible, weak pulse. The genito-urinary system was normal, as far as could be ascertained by symptoms and the examination of the urine.

On August 17, the blood was examined microscopically. The corpuscles were irregular in shape, many were smaller than natural, and they were all very deficient in coloring matter. They had a great tendency to run together—not into *rouleaux*, but to form an irregular fused mass. The white corpuscles were not greatly increased, but the red were very much diminished. When enumerated by means of Dr. Gowers' hæmacytometer, they were found to be only 32 per cent.

The patient daily became weaker, and the corpuscles diminished in numbers; on August 27 they were only 30 per cent. The vomiting still continued, and the emaciation and anæmia increased. On September 26 the proportion of red corpuscles was reduced to 26 per cent., and the hæmoglobin only 11 per cent.

On September 27 she insisted on going home.

It was ascertained afterwards that the patient had been taken to Guy's Hospital, where her extreme anæmia was noted as the marked feature of the case. She died in a very short time, and at the post-mortem examination, which was made by Dr. Peter Horrocks, a scirrhus of the pylorus was found without ulceration, and a small cancerous mass in the uterus.

Note (by Dr. Barlow).—The special features of this case was the intense pallor, so that but for the detection of the small mass, proved afterwards to be scirrhus of the pylorus, it might have been considered one of idiopathic anæmia. It is important to bear in mind that there was no ulceration of the mucous membrane. The benefit derived, during the few days of its administration, from the pancreatized oatmeal-gruel recommended by Dr. William Roberts was most striking, and if only the patient had been willing to persevere with it she might have been saved a great deal of distress. In another similar case this preparation was used with the greatest advantage for over two months, during the early part of which there was very marked improvement in general nutrition; but the patient ultimately succumbed, with extensive deposits in other organs.—*Medical Times and Gazette*, November 11, 1882.

Palpebral Chancre.—M. Delapersonne (*Arch. d'Ophthal.*) of the ophthalmic clinic of the Hôtel Dieu, contributes a didactic article on the etiology, physical characters, symptoms, diagnosis, and treatment of chancre of the lid, with a brief analysis of two cases occurring in the service of M. Panas, Hôtel Dieu, in 1881, and of a case of M. Fournier. Some of the major observations that have from time to time been made by Gælezowski, Panas, Ricord, Julien, Wecker, Desmarres, Mackenzie, and others, are referred to for the assistance of the bibliophile in this department of ophthalmic study. While the author does not deny the possibility of a simple chancre of the lid, he dwells upon its rarity, and emphasizes the only true support such diagnosis can have, viz., its physical characters, and the absence of secondary symptoms, even several months after the healing of the chancre. The etiological factors are here, as in the general sphere, hard to prove. Contagion can be attributed to the projection of saliva, or to fluids charged with syphilitic virus. Patients usually have a ciliary blepharitis antecedent to an ulcer or little ulcerations of the free border of the lid. Phenomena of inflammation are wanting. Patients complain of no pain, nor labor in lid-movements, nor of lachrymation, nor perhaps of deformity.

The physical characters of lid-chancre are variable according to their seat. The most common habitat is the inferior lid, either the cutaneous surface or the free border. As a special adenopathic involvement, the preauricular ganglion takes precedence; after this, the ganglia at the angle of the jaw, and the submaxillary region. It is well known that the lymphatics of the lower lid and inner canthus find their way through the facial vein into the submaxillary and sterno-mastoid ganglia.

When situated at one of the commissures, the chancre takes the form of a fissural ulcer, precisely limited by the free border; on this account the diagnosis may be misconceived, the ulceration being like that following a chronic dacryocystitis. The induration and ganglionic engorgement will prevent the error.

Most rarely the chancre occupies the internal surface of the lid. Inflammatory symptoms are here the most intense, as conjunctivitis, corneal ulceration, and iritis.

After the cicatrization of the chancre, induration persists, even to the concealment of the lachrymal puncta, and their obliteration. Cicatricial bands may unite

the two folds of conjunctiva, and constitute a true symblepharon, with results even more serious than the chancre itself.

The diagnosis of lid-chancre is to be eliminated from that of a furuncle, chalazion, lupus, and cancer. The last has an irregular, slightly elevated border, field covered with papillæ, the skin cut out at the circumference, cauliflower in its appearance, and easily bleeds. An invaluable distinctive mark of cancer is the advanced age of the patient, and exceedingly slow march of the sore.

In order to attain the size of a chancre, an epithelioma of the lid sometimes occupies several years.

More difficult is the diagnosis of chancre from lupus, which it most resembles; but the less rapid advance of lupus, its occurrence in young persons, and the absence of lymphatic involvement usually suffice as characteristics of distinction. As a final test of diagnosis, the sore thould be inoculated elsewhere on the patient, and the latter be kept under observation for several months.

Three cases are adduced in brief summary.—*Arch. of Dermatol.*, October, 1882.

The Traumatic Origin of Loose Bodies in Joints.—In France, and Germany especially, the statement that in falls and blows upon the knee or other joint a portion of the normal articular cartilage and bone can be broken off and remain in the joint as a "loose body," has met with much opposition. In England this view has met with more general acceptance, and in modern special treatises and text-books no doubt is thrown upon it. On the one hand, cases are cited where persons with apparently perfectly healty joints have after a fall or other severe local injury shown all the symptoms of "loose body;" and it has been found in some cases that corresponding more or less exactly with the outline of the loose body is a gap in the joint surface of the femur and tibia. On the other hand it is alleged that in these cases, although there may have been no previous signs of joint disease, there were really outgrowths from the articular cartilage that were broken off by the injury. In the gradual enlargement of these supposed outgrowths, the pressure upon the opposed joint surface has caused its absorption to an extent corresponding to the size of the outgrowths. This view will be held by most surgeons to be fanciful, and not to accord with the most simple and straightforward interpretation of the facts, and it has been rejected in this country. M. E. Poncet, of Ciuny, has approached this question from the histological point of view in a paper in the last number of the *Revue de Chirurgie*. Here he states that in capsular "arthrophytes" a gradual transition from cartilage through fibro-cartilage to true bone is not unfrequently met with, that there is sometimes calcification of the fibro-cartilage quite distinct from true bone, that in all specimens a hilus or remains of a pedicle are to be seen, while in none is there any capsule of newly formed fibrous tissue surrounding the loose body. In true traumatic "arthrophytes" he found, on the contrary, no hilus or sign of any pedicle, but the body was surrounded by a thin cortex of newly formed fibrous tissue, while a section showed that the line of separation of the bone and cartilage was sharp and abrupt, and without any intermediate zone of fibro-cartilage. The bony matter, too, was always placed to one side of the body, and was never completely surrounded by cartilage, but partially in immediate contact with the cortex of fibrous tissue which was found to be histologically continuous with the cell tissue in the cancelli. These observations certainly afford a further proof that "arthrophytes" may be produced by injury to previously perfectly healthy joints. M. Poncet advocates the removal of "loose bodies" through a sufficiently free incision, but he disapproves of the subsequent use of a drainage-tube. Regarding the drainage-tube as solely intended to prevent the exudation from the wound passing into the joint, he endeavors to secure this object by suturing the synovial membrane with fine catgut, and closing the external wound in a similar manner. As M. Poncet mistakes the object for which the drainage tube is used in such cases, his argument upon it is misleading. The tube is used to run off any excessive secretion from the synovial membrane that may be caused by the interference of the operation. M. Poncet's successful case only shows that in it this secretion of synovial fluid did not occur, and it would be rash in the extreme to argue from it to all cases of a like nature.—*Lancet*, November 11, 1882.

Artificial Feeding of Infants.—Dr. Tarnier recently read an interesting communication on the above subject before the Academy of Medicine of Paris. Although artificial feeding is considerably less common, we believe, in England and this country than in France; nevertheless there is far too much of it; and the high rate of mortality of infants under one year of age is unquestionably very largely due to the want of care in the choice and the employment of artificial foods during infancy.

Owing to the unsatisfactory nature of artificial feeding in France, the Academy placed the subject among its prize questions in the year 1878; but nothing very definite resulted from the sixteen essays which were sent in—partly on account of the uncertainty that prevails as to which is the best milk to use for the purpose. The milk of the ass, of the goat, and of the cow are the most employed. M. Tarnier contends that the milk of the ass most nearly resembles, chemically, that of woman, and has been used for a long time past, although not, indeed, extensively.

He urged on the Academy the need of initiating reform in this matter, and concluded his paper by formulating certain proposals, from which we select the following: 1. The life of young infants can only be preserved by maternal nursing. This must, therefore, be encouraged by every means in our power. 2. If the mother's milk is insufficient, it may be supplemented by other food. 3. Suckling by a wet-nurse is favorable for the nursling, but detrimental to the nurse's own child. 4. Artificial milk is much inferior to maternal milk: its use is always surrounded by considerable difficulties, however we may try to avoid them, and whatever milk we use. It should never be had recourse to except when essentially necessary. 5. To solve many of the difficulties inherent to the subject it would be well for the Academy to undertake an experimental inquiry. The subject is one of great interest, and as pressing in large cities in England as in Paris.—*Med. Times and Gaz.*, Nov. 11, 1882.

Iodide of Potassium in Skin Diseases.—Greve (*Nordisk med. Arch.*, xiv., No. 1, 1882) recommends large doses of iodide of potassium in skin diseases, especially psoriasis. He begins with a mixture of iodide of potassium, 10.00 to 300.00 water, of which he gives a tablespoonful three or four times a day. Every time the prescription is renewed five grammes are added. He always increases the strength to 30.00 iodide to 300.00 water, and has, without inconvenience, given as high as 40.00 to 300.00. As soon as the dose of one gramme is reached, an effect is produced on the skin lesion. If the dose is limited to one gramme, or one and a half, the improvement is gradual, but if the amount is increased to 2.00 or 2.50 grammes, the improvement is rather rapid. The less affected parts of the face are first cured; next, the eruption on the neck,

chest, and back disappears; and last on the extremities, where shining cicatrices often remain because of thickness of the parts. Greve has given the drug both to adults and children, and never seen any injurious effect from its administration.—*Arch. of Dermatol.*, October, 1882.

COMPLETE INVERSION OF THE UTERUS.—At the meeting of the Cambridge Medical Society, held October 6, MR. WHERRY related a case of complete inversion of the uterus. The patient was a woman who had been delivered two days previously of a healthy male child, which was born rather suddenly and with a short thick cord. She was given twenty minims of liquid extract of ergot after delivery, and shortly after this had a pain, and there was protruded from the vagina what at first appeared like the head of another child, but which proved to be the inverted uterus, with the placenta adherent. There was not much hemorrhage. The medical attendant detached the placenta and endeavored to replace the uterus by his hand, but he was obliged to desist, owing to the great softness of the uterine walls and the collapsed condition of the patient. Two days later, when called in, Mr. Wherry found the uterus completely inverted. Ether was administered, but it was quite impossible, owing to the doughy softness of the fundus, to replace the uterus with the unaided hand. Accordingly a large rubber drainage-tube was inflated to about the size of an egg at one end and ligatured. The hand, in the form of a cone, was passed into the vagina, and the finger tips, pressed against this air pad, were in no danger of lacerating the walls of the uterus. Half an hour's pressure, first with one hand, and then with the other, against the most prominent part of the fundus, at length reduced the uterus, leaving the dilated tube in the cavity. The string was then cut and the collapsed tube withdrawn. The replacement was not by a jerk, but gradual, and to be compared to the relief of a paraphimosis; it was evidently effected by squeezing fluid out of the œdematous tissues of the uterus. The patient, after three days of fever and pain in the body, made an excellent recovery.—*Lancet*, November 11, 1882.

TREATMENT OF JOINT AFFECTIONS BY ELECTRICITY.—DR. A. JOFFROY, writing in the *Archives Générales de Méd.*, says that electrotherapy is only efficacious in cases of chronic arthritis, and is contra-indicated when the acute and subacute phenomena have not disappeared, In the joint affections of progressive chronic articular rheumatism, the results are but small; and when they are successful, they may be rather attributed to rest than to electrotherapy. In chronic articular rheumatism with uncertain localization and progress, and especially in the chronic forms of arthritis, consecutive on blennorrhagia, the puerperal state, or injury, more satisfactory results are obtained. The operation consists in fixing the positive pole of a continuous current battery, with from twenty to forty elements, either on the sides or on the upper or lower portion of the swollen joint, and moving about the pad representing the negative pole over the cutaneous surface. The skin becomes red and sensitive where the pad is applied. In the successful cases, the lesions were situated especially on the tissues surrounding the joint, which were indurated and resistant. There were neither fungosities, nor osseous lesions. This clinical fact explains why this treatment does not yield favorable results in gout and in chronic articular rheumatism. It is, therefore, especially in affections of joints, produced by wounds. by the puerperal state, or by blennorrhagia, but only after the disappearance of all the acute symptoms, that the continuous current may bring on either a complete cure, or at least a rapid improvement of the circum-articular changes and the restoration of movement.—*London Medical Record*, November 15, 1882.

TÆNIA IN A CHILD SEVEN MONTHS OLD.—DR. SCHOPFF communicates this excessively rare case, occurring in a female child only seven months old, in whose fæces the proglottis of the *tænia circum rinaelliptica* were found. According to the most recent researches, the cysticerci of this tænia are found in dogs' lice, and the dogs become infected by swallowing the parasites. Consequently the appearance of this parasite can only be explained in persons who are brought into close contact with dogs. In the case reported it was found that the child had been accustomed to play with a dog affected with some skin disease accompanied by falling of the hair.—*Ann. de Gynécol.*, November, 1882.

GONORRHŒAL RHEUMATISM.—DR. W. NOLEN terminates an elaborate article on gonorrhœal rheumatism somewhat as follows: While occasionally gonorrhœa is complicated by a rheumatic affection, such cases are very rare in proportion to the immense number of cases of gonorrhœa not so complicated, and even when present, the rheumatism may be of the most diverse nature and intensity, and possesses no distinctly characteristic features. It seems to be fairly well established that when once an attack of gonorrhœa is complicated by rheumatism, it is also present in subsequent attacks, indicating the probability, in some unknown manner, of the causative action of the gonorrhœa; though it may also be held that the principal cause lies not in the gonorrhœa, but in the constitutional tendencies of the individual, the simultaneous occurrence of gonorrhœa and rheumatism being merely coincidences.—*Deutsches Arch. f. klin. Med.*, November 8, 1882.

INTESTINAL STRANGULATION; LAPAROTOMY; CURE.—In the presence of intestinal obstruction by volvulus, invaginations, or adhesions, choice must be made, according to M. LÉON LE FORT, between enterotomy and laparotomy. He prefers the latter procedure, because it, equally with the former, permits an escape of the obstructed intestinal contents, and enables the removal of the cause of the obstruction. In support of this opinion he cites the case of a young man of eighteen years, who for six days had suffered from the symptoms of strangulation. M. Le Fort performed gastrotomy under chloroform, an incision 15 centimeteres long being made in the linea alba from the umbilicus to just above the pubis; the peritoneum was then opened and the intestines carefully searched for the obstruction, which was finally found in the form of an annular constriction formed by inflammatory adhesions, about 5 centimetres above where the ileum entered the cæcum. The constriction was divided, the intestines returned to the abdominal cavity, and the wound closed. One month later recovery was complete. The antiseptic method was not employed; compresses soaked in dilute camphorated alcohol being retained in position by a body bandage.—*Gaz. Hebdomadaire*, Nov. 10, 1882.

LIGATURE OF THE EXTERNAL ILIAC ARTERY FOR FEMORAL ANEURISM.—At the meeting of the Société de Chirurgie held on October 25th, M. BERGER presented a patient in whom a popliteal aneurism had been cured by digital compression on the femoral artery. Some time afterwards a second aneurism formed on the femoral artery at the point where the vessel had been subjected to pressure in the treatment of the popliteal aneurism. Ligature of the external iliac artery resulted in a cure.—*L'Union Méd.*, October, 31, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, DECEMBER 9, 1882.

HOUSE-DRAINAGE.

IN a recent issue we presented the results of late investigations of the sewerage system of Philadelphia, and endeavored to illustrate thereby the defects which commonly appertain to most systems of sewerage as constructed at the present day in this country. At this time, we desire to call attention to an equally important subject, that of house-drainage, and the faults commonly connected with it, as exemplified by some of the methods pursued in Philadelphia, and elsewhere. Fresh interest has been given to the topic by the recent enquiries of Rudolph Herring, Assistant Engineer, of Philadelphia, and W. H. Baldwin, C. E., who acted under special authority of the U. S. Census Bureau. They show how, in the absence of specific sanitary regulations on the subject, the most pernicious errors creep into practice, and are repeated day by day, until at length they become more or less characteristic of the entire system.

Formerly, before the sewers were made use of for the conveyance of domestic waste, it was the custom to construct, on the lot in the rear of the dwelling and sometimes under a portion of the dwelling, deep cesspools, or wells as they are called, which were excavated down to the gravel-bearing strata, and lined, except at the bottom, with brick laid dry, so that the liquid portion of the contents might flow off through the pores of the soil. These wells were used for the deposit of excreta and chamber slops, and seldom needed cleaning on account of their depth and manner of construction. When cleaning was required, it was done by the "bucket and cart" system until recently, when the "odorless system," by means of tank, pump, and hose, was introduced in its place.

Since the introduction and common use of water-closets, there has been a gradual development of a practice of turning all the wastes of the house into these cesspools, their connection with the water-bearing strata underlying the city being depended on for carrying away the liquid portion as well as a quantity of the more finely divided solid matter. In course of time, however, the pores of the soil become obstructed, the well fills up, and has to be emptied by mechanical appliances. The constant expense and annoyance caused by this need has led to the adoption of another device, namely, that of tapping the well at a convenient level and connecting it by means of a drain-pipe with the common street-sewer, so that the overflow is discharged into this outlet. To prevent the accumulation of solid matter and the occlusion of the overflow-pipe, the rain-water and bath-water are likewise turned into the well. This is substantially the plan of drainage connected with a large number of the older houses.

But this method of disposing of sewage is not alone confined to this class of buildings. In houses of more recent construction, especially such as are called "bonus houses," the drainage arrangements are constructed upon the same principle, except that the wells are not required to be deeply excavated, nor to have pervious walls and bottom. The plan is to construct a cesspool in the rear to serve for two houses. The rain-water as well as all the sewage from the houses are discharged into it. These cesspools are about seven feet deep, and four feet in diameter. They are walled up with brick, and are intended to be coated inside with cement, so as to be water-tight, but in most cases the bricks are laid dry, thus permitting the escape of liquid matter into the surrounding soil. Each well connects directly with the street-sewer by means of a terra-cotta pipe; or, as is more commonly the case, each well is connected with a terra-cotta drain placed under the alley-way between the rears of two rows of houses, which drain has its outlet in the sewer in the street. In other cases the cesspools are used solely for excreta and chamber slops, while the kitchen slops and surface drainage are allowed to flow over the surface of an alley-way in the rear of the house, or between two houses into the street-gutter, to find their way into the nearest street-gulley. Most of the better class of houses have independent sewer connections, by means of iron or terra-cotta pipes, generally the latter, which are constructed above or beneath the cellar floor, and enter the sewer in front of the house, or are laid under the surface of the lot in the rear and connect with the sewer in the back street. Through these channels the entire drainage of the premises, including bath,

surface, and roof water, is conducted directly into the sewer, and the cesspool nuisance is avoided.

The plans mentioned above, serve to illustrate the common faults connected with the private disposal of domestic sewage. In the first place, the storage of excreta and other putrescible matter in close proximity to habitations, is a practice which is repulsive to our senses, and in a high degree detrimental to health, and as such cannot be too severely condemned. Even when water-tight and well-ventilated vaults are used, and their cleansing is periodically attended to, the practice is objectionable, from their liability, even with these precautions, to become nuisances in the course of time.

But this care in construction and management is the rare exception, the rule being to construct these receptacles in such a manner that as much as possible of their contents shall be carried away by percolation into the ground. The result is the pollution of the soil, air, and when wells for the supply of drinking water are in close proximity, the pollution also of this supply. Shallow cesspools connected with the street-sewer by an overflow pipe, into which kitchen wastes and bath-water, as well as excreta, are discharged, produce the same train of evils. It frequently happens that the outlet-pipe becomes obstructed, causing the contents of the pit to overflow and defile the surface of the ground, and even the foundations and cellar of the dwelling. When the drain-pipe has a separate connection with the sewer, the remedy is easily applied; but when it is a part of a system common to a large number of houses, an obstruction in the main drain is not so quickly remedied on account of the difficulty of locating the obstruction, and from want of agreement and united effort on the part of the numerous property owners. The result is the perpetuation of a series of nuisances of the very worst description, until the intervention of the health authorities is invoked in behalf of the preservation of the public health. Nothing short of complete reconstruction of the drainage arrangements, and the separate sewer-connection of each property, avails to abate the evils inseparably connected with this radically defective plan of house-drainage.

There are two or three phases of the evil consequences of the storage of household wastes upon the premises that may be briefly alluded to. The retention of this material in cesspools and its constant agitation at a moderately high temperature, caused by the influx of hot water and other substances favors the decomposition of the organic matter, and the evolution of noxious gases which escape into the surrounding atmosphere. In a thickly populated neighborhood where there are nearly as many depositories of filth as there are habitations, the combined action of these mephitic vapors must have the effect of seriously polluting the air and rendering it offensive, if not unsuitable for sustaining the normal condition of the vital powers of the system. The occupants of such houses are also subjected to dangers arising from polluted soil and contaminated ground-air. Leaking cesspools (and there are few that cannot properly be embraced in this category) have the effect of loading the soil with impurities, and of imparting a deleterious quality to the air circulating through it. The aspiratory power of the warmer air of the house in most months of the year produces a current of vitiated air, from the sublying and surrounding soil, into the basement, whence it ascends throughout the house.

It is a well-known fact that one of the chief causes of the foul condition of the sewers is the discharge into them of decomposing excreta and other organic matter. If house-sewage escaped in a fresh state, and sewers were properly constructed so as to insure the ready and quick removal of this matter before decomposition sets in, the evils most complained of would be averted.

With regard to the plumbing arrangements of houses, there is nothing specially to report which is not common to almost all American cities. The best and the worst and all intermediate grades of work exist, as might be expected when the matter is left entirely in the hands of the owners of property and mechanics. Owners, as a rule, have not the special sanitary knowledge required in designing and supervising the work; and mechanics can hardly be expected to execute the most skilful labor when their financial success depends so largely on the greatest economy in construction. Their lack of knowledge of the correct sanitary principles of house-drainage, is also a very frequent cause of defective work. The remedy is found in the public regulation and supervision of house-drainage. This plan has been applied with great benefit in Providence, R. I., and has also recently been inaugurated in New York City. The regulations adopted by New York Board of Health may be found in full in our issue of November, 1881.

The evils which result from defects in plan and execution of house-drainage, as exemplified by the methods pursued in Philadelphia, are to be remedied: 1st. By prohibitory laws with regard to cesspools and pits of every description. 2d. By compulsory laws on the subject of sewer-connection where sewers exist; and in their absence, by the enforced adoption of the "dry-removal" system. 3d. By the systematic regulation and supervision by the civil authorities of the details of private drainage arrangements, and by periodical inspection by properly qualified public officers.

POLYGONUM HYDROPIPEROIDES (WATER PEPPER, SMARTWEED).

American physicians seem hardly to appreciate the wealth of resources contained in our indigenous materia medica. The *hydropiper* is an illustration. This remedy is not even mentioned in our pharmacopœia. Yet the late Dr. Eberle, in his work on Materia Medica and Therapeutics—in its day a deservedly popular treatise—speaks of it as the most active and certain of the emmenagogues. The late Prof. M. B. Wright, of Cincinnati, held it in equal estimation, and during his long career prescribed it often with remarkable success.

There is a curious history connected with the introduction of this drug into medical practice. Eberle obtained his knowledge of it from a country practitioner, who made it the subject of his thesis as a candidate for the doctorate, at the medical school where Eberle then held the chair of practice. Successful experience with it induced him to give an account of its actions and uses in his therapeutical treatise, but he does not state the source of his information.

The activity of this drug is due probably to the presence of *polygonic acid*, which is contained in its congener, *Polygonum hydropiper*. It has very decided stimulant, even vesicating property, when rubbed into the skin, whence its common name—*smartweed*. As an emmenagogue, it is indicated in states of anæmia, functional torpor of the ovaries and uterus due to systemic depression, and is contra-indicated in the condition of plethora. It should be given for several days before the time for the menstrual molimen to begin. It need hardly be stated that the non-existence of pregnancy should be assured before prescribing this or any other uterine and ovarian stimulant.

Whilst the water pepper is thus indicated in anæmia and functional depression, its power to stimulate the uterine circulation renders it useful in menorrhagia, and in metrorrhagia due to relaxation of the uterine vessels. Sub-involution of the passive kind, with a sluggish circulation, cold hands and feet, and general depression, are also benefited by this remedy.

The form most convenient for the administration of this drug is the fluid extract, given from five to thirty minims, three or four times a day. Its taste is hot, pungent, and somewhat acrid, but when mixed with some glycerine and wine, it can be readily taken.

THE GARFIELD BOARD OF AUDIT.

It is a matter of honor, as well as of custom, that the indebtedness for medical attendance in the last illness should be promptly paid. The amount to which the bills in the case of President Garfield have been "scaled" by the Board of Audit is totally inadequate to the services rendered, and this indisposition on the part of the Government to justly meet them is the foundation of another scandal, of which the people would gladly be spared the disgrace.

When President Garfield was shot, and his life was still hanging by a thread, our horror-stricken nation demanded that he should have the benefit of the united wisdom of the best surgical skill that was attainable. Drs. Agnew and Hamilton were, therefore, summoned to Washington the day after the assassination, and, in conjunction with the surgeons there, gave to the distinguished sufferer their sole care and unremitting attention during those weary days in which the eyes and sympathies of the whole world were centred at his bedside.

When Congress assembled, it properly expressed public sentiment in declaring that the personal expenses of the President, resulting from his assassination, should be assumed by the Government, and it promptly passed an appropriation for the payment of the funeral expenses; which, to the scandal of the nation, included a considerable sum for wine and cigars consumed by the Congressmen who escorted the remains from Washington to their final resting-place. And this Congress—the same which, in the "log-rolling" river and harbor bill, appropriated upwards of $20,000,000 to be expended where it would do most good in promoting the re-election of its members—with considerable display of virtue, assumed that the Government ought not to appropriate so large a sum as $65,000 in payment of the services of the surgeons who were summoned, at the request of Mrs. Garfield and members of the Cabinet, to attend the wounded President. After wrangling over the subject all winter, Congress finally decided to give to a "Board of Audit" $35,000 with which to settle these accounts.

In making an estimate of the value of their professional services, Drs. Agnew and Hamilton explicitly stated that it was calculated at the rate at which they were ordinarily paid by well-to-do-patients for services rendered out of the city and requiring the same amount of time. This was their only criterion, as no similar case has ever happened before, and God forbid that it ever happen again!

The Board of Audit received the bills, and then, in consonance with the expressed feelings of the body that created it, have "scaled" them down to $20,500, and, as if to still further depreciate the services of the surgeons, they have awarded $7000 to Drs. Boynton and Edson, who were employed in the case solely as nurses.

Such is the manner in which it is proposed that the nation shall remunerate the men who, at its demand, and at great personal sacrifice, without stop-

ping to ask who would pay them, or even whether they would be paid at all, dropped their private business and took charge of our wounded President, and at the same time accepted a weighty care, and well-nigh crushing responsibility, greater than which surgeons never before assumed. Under the circumstances they can much better afford to remain unpaid than to accept the paltry sum at which the Board of Audit estimates the value of their services.

A NEW BOGUS DIPLOMA-MILL.

WE had supposed that the bogus diploma institution in America was a thing of the past, but we have lately received a photograph of a diploma issued by the Bellevue Medical College of Massachusetts—an institution incorporated May 25, 1880, in accordance with the "Public Statutes relating to *Manufacturing* and other Corporations organized under General Laws." Consistently with its mode of origin, this mill has commenced to manufacture diplomas in a manner which would have done credit to the hydra-headed establishment of which Philadelphia has been so fortunately rid. The diploma, written in Latin, contains the usual salutation to all who may read, and confers the degree of Doctor of Medicine upon John Burton Thompson, *hominem egregium studiis optimis deditum*—a distinguished man, devoted to the noblest pursuits—and is signed by Rufus King Noyes, M.D., President, and May R. Eastman, Secretary, but without the signatures of any Faculty.

The nefarious practices of this new-fledged diploma-mill have been uncovered by the vigilance of the State Board of Health of Illinois, which, under the direction of its active Secretary, Dr. John H. Rauch, has probably done more to break up the irregular issue of medical dipolmas than any other body. The result was accomplished much as Mr. John Norris, of the Philadelphia *Record*, secured the overthrow of the diploma traffic in this city. A letter was sent, purporting to have been written by one V. B. Kelly, accompanied by an essay on "Vaccination," which, with the letter, was such a marvel of bad spelling that it should have betrayed its real purpose to a man of ordinary mental acumen. Under the plea of poverty, the writer applied for a "diplomy" without being put to the expense of attending lectures, and, after very brief negotiation, one was sent to him by express, C. O. D., for $150.

We have seen it somewhere stated in the daily press that Rufus King Noyes, M.D., disclaimed any knowledge of this practice of the school of which he appears as President; but the methods of advertising pursued on his business card, and a certain local notoriety he has made for himself in Lynn, Mass., as an antivaccinationist, betray his tendencies, if not his real character.

We sincerely hope that the Commonwealth of Massachusetts will act more speedily than did our own State authorities in repealing the charter of this disgraceful *manufacturing* establishment, and deal promptly with the offenders, as they must be, against the law of the State. In the meanwhile we are glad to learn that the government authorities have secured the arrest of Eastman for violating the U. S. postal laws.

WILL THE NEW YORK CODE BE MAINTAINED?

THE medical profession of the country, from Maine to California, have, with absolute unanimity and in terms not to be mistaken, expressed their unqualified disapproval of the New Code adopted at last year's meeting of the New York State Medical Society, and the medical press, with but two exceptions, have correctly represented professional sentiment on the subject. The *Medical Record* and the *New York Medical Journal* alone have championed the New Code, and sought to lead the profession to giving its countenance to charlatanry, but their teachings appear to have in no wise swerved professional morals or influenced professional opinion, not even in their own State. Outside of the City of New York, the New Code seems to be without support, at least if we can judge by the fact that thirty-three of the county societies have formally repudiated it, and but two have accepted it. It is, therefore, no longer a question of doubt that a great majority of the delegates to the State Society are opposed to the New Code, and it only remains to be seen if, at the approaching meeting, the large pledged delegation from New York City can, on a required two-thirds vote, override the will of the rest of the State.

BODY-SNATCHING.

As we go to press we learn that, through the enterprise of one of our city newspapers—*The Press*, a colored man and two wagon-drivers have been arrested for robbing graves in one of our cemeteries. We have only space at this time to express in the strongest terms our condemnation of this crime.

The law of 1867 directs that unclaimed bodies shall be delivered to the medical colleges for dissection in proportion to the number of their students. Why, then, it may be very properly asked, should there exist any cause for body-snatching? The chief reason is, because the Coroner of this city persistently disregards and disobeys this law.

The number of subjects received from the Almshouse is utterly inadequate to meet the needs of the large number of medical students in the city, and the Jefferson Medical College, we have the best authority for stating, has in several years received

less than a dozen subjects from the Coroner, while his own private rooms for anatomical instruction have had an ample supply.

It is only a question of time when the Coroner must be compelled to obey the law of the Commonwealth, of which he is a sworn officer, or better still when he and his office shall be things of the past.

IN commenting on the clinical teaching of obstetrics lately, we took strong ground in favor of it. As a forcible commentary upon this, we quote from a letter just written by a young medical friend—a recent graduate—now studying in Vienna, and we commend it not only to boards of guardians of the poor, but to the philanthropists who have at heart the best good of poor women. The rich can afford to pay for experienced able men, the poor cannot. But let our correspondent tell the result.

"I graduated without ever having examined a pregnant woman or seen a single delivery, and was licensed to go out and get experience at the expense of my earlier patients. But the first two weeks I was here [there are 10,000 births a year] I saw two craniotomies, several forceps cases, and numerous births, and in a month I have learned more of practical obstetrics than in a whole winter of didactic lectures. All that mass of material at the Almshouse is only of benefit to a very few men. That is the system that drives men abroad who wish to have some experience before they practice."

REVIEWS.

ESSENTIALS OF VACCINATION; A COMPILATION OF FACTS RELATING TO VACCINE INOCULATION AND ITS INFLUENCE IN THE PREVENTION OF SMALLPOX. By W. A. Hardaway, M.D., Professor of Diseases of the Skin, in the Post-Graduate Faculty of the Missouri Medical College, etc. Pp. 146. Chicago: 1882.

THIS is a useful and timely work. Dr. Hardaway presents in a small compass the "essentials of vaccination," which must be regarded as a necessary, and as indeed an indispensable, duty, to be undertaken by some one. It is fortunate that the task has been undertaken by some one so well qualified to perform it as is Dr. Hardaway. The advantages of this libellus are obvious. It is small, condensed, and therefore within the reach of any one almost. The knowledge is accurate and well put. Those who read it cannot fail to receive correct notions. The hand-book of Dr. Seaton is an excellent work, but, compared with this, is both voluminous and expensive, and, besides, has for some time been before the profession without revision. Furthermore, Dr. Hardaway's book contains a good deal of matter of American origin. There are chapters on the history of vaccination, on variola in animals, on the nature of vaccinia, on vaccinia in the human subject, on abnormal modifications and complications of vaccina, on revaccination, on the merits of different kinds of vaccine virus, on the methods of obtaining and storing the virus, on the operation of vaccinating, and, finally, an examination of the objections to vaccination. All of these topics are treated with sufficient detail, if somewhat sketchily. On the whole we can recommend the work to our readers as a useful and convenient treatise on this topic.

ATLAS OF GYNECOLOGY AND OBSTETRICS. Edited by DR. E. MARTIN, Prof. of Gynecology at the University of Berlin, and DR. J. P. MAYGRIER. Containing 475 plain and 35 colored Illustrations. THE EXPLANATORY TEXT, TRANSLATED and EDITED, with ADDITIONS, By WM. A. ROTHACKER, M.D., Pathologist to the Cincinnati Hospital, Ohio. Cincinnati: A. E. Wilde & Co.

THIS atlas consists of fifteen parts, each containing four plates and four pages of explanatory text. In all, there are over four hundred illustrations, many of them beautifully colored, and covering completely the subjects of gynecology and obstetrics. Many of these are reproduced from the well-known *Hand Atlas* of Dr. A. Martin, of Berlin; the remainder are lithographic copies of Maygrier's *Nouvelles Demonstration D'Accouchements*. This American edition is translated and edited by Prof. Wm. A. Rothacker, pathologist to the Cincinnati Hospital, the explanatory text of the obstetrical portion being written altogether by Dr. Rothacker. Such drawings are of great value to all students and practitioners of gynecology and obstetrics, and will prove almost indispensable to teachers of these branches of medicine.

SOCIETY PROCEEDINGS.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, November 23, 1882.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

GREAT HYPERTROPHY OF THE HEART DUE TO SEVERE VALVULAR LESIONS.

Presented by DR. M. O'HARA.

J. K., male, æt. 30 years, laborer, contracted syphilis when 18 years of age. Health good until within past three years, when he began to suffer from pain in the left breast, palpitation of the heart, and slight dyspnœa after violent exertion. Gradually becoming worse and unable to work, he was admitted into St. Mary's Hospital in June, 1882. He then complained of great pain over the upper part of the sternum, in the left arm, and shoulder. He lost considerably in weight, his appetite was poor, and albumen was present in small proportion in his urine, although casts were absent. He had marked dyspnœa on admission, which increased rapidly until sleep could only be obtained in the upright position. There was no evidence of pulmonary trouble. With the forearms flexed to a right angle the brachial arteries became prominent at each impulse of the heart; the pulsation of the carotids was wavy and prolonged; the temporals were tortuous and visibly pulsated; no retinal arterial pulsation was seen. Retinal venous pulse was marked, but no visible venous pulsation was detected elsewhere. The left præcordial region was specially prominent. The apex beat was most distinct in the sixth and seventh interspaces on a perpendicular line running midway between the left nipple and anterior border of the left axilla. The heart's impulse was usually forcible and diffused, but at times it became weakened and wavy. In the second left intercostal space a systolic impulse was observed. The pulse rate varied from 80 to 120 per minute, struck the finger with considerable force, but at once lost

most of its volume. All these phenomena were exaggerated by raising the hands above the head. The radial pulses were unequal, but the brachial arteries presented no differences. No hepatic pulsation was felt. The cardiac area of complete dulness was nearly twice its normal size, the increase being downward and to the left. Over the second right costo-sternal articulation, the closure of the aortic valves was distinctly heard, and with this a slight diastolic murmur. A systolic murmur was also heard over the same spot. The systolic murmur was nearly lost in the carotid and subclavian arteries, but the diastolic one remained distinct. On a line with the second costal cartilage, over the sternum and to the left of this bone, the diastolic and systolic basic murmurs were most intense. Over the cartilage of the left fourth rib, the murmurs heard at the base of the heart were less distinct or were obscured by the development of other murmurs. In this situation a short, sharp, presystolic murmur, apparently prolonged into a systolic one, was detected. At the apex and just above it, the systolic murmur became intensified, its blowing character aiding in differentiating it from the short, harsh murmur which immediately preceded it. From the fourth to the seventh rib, and from the sternum to a point about five or six inches to the left, a diastolic murmur of considerable intensity was heard. The character of the diastolic murmur over this area was different from that presented by the second sound murmur at the base of the heart, and its intensity was much greater. Posteriorly, at the lower angle of the left scapula a blowing systolic murmur, entirely deprived of its harsh presystolic complication, was heard. Dr. Eskridge thought the physical signs justified him in venturing the diagnosis of constriction and regurgitation at the ventral orifice; a rare form of aortic regurgitation produced by the inability of one of the aortic semilunar valves to close while the others acted properly; great hypertrophic dilatation of the left ventricle, and to a less extent of the left auricle; and aneurismal dilatation of one of the great vessels, probably of the pulmonary artery near its origin from the heart. The patient rapidly sank, œdema of the lower portion of the trunk and lower extremities, with hydrops pericardii, of the pleura, and of the peritoneum, developed. He died exhausted in August, nearly two months after admission to the hospital.

Sectio-cadaveris.—Brain: Some venous congestion of the pia-mater. The brain substance and the ganglia nearly normal in appearance. Thorax: The pericardium was nearly filled with serum. The only evidences of inflammation were a few patches of recent lymph at the left anterior upper portion of the sac. The heart weighed eighteen ounces, the increased weight being chiefly due to eccentric hypertrophy of the left auricle and ventricle. The right ventricle was dilated, with slightly thickened walls. The aortic valves were insufficient and thickened. The posterior leaflet was normal in shape, but the others curled upon themselves on the aortic side of the orifice. The stenosis was slight. The mitral orifice was button-hole shaped, and the valves failed to close on account of calcareous deposits in their tissues, this degeneration also involving the inner surface of the left side of the auricle contiguous to the valves. The auricular surface of the valves was fairly smooth, but in the ventricle just beyond the valves, and attached to them, hung a bony substance about one-eighth of an inch in diameter. The left auricular appendix was much hypertrophied. The valves at tricuspid and pulmonary orifices were normal. The pulmonary artery was considerably dilated. The pleural cavities contained several ounces of serum. There were old adhesions at the apex of the right lung posteriorly, and at the same part of the left lung anteriorly. Several patches of recent lymph were also found at the lower part of the left pleural cavity. Abdomen: The peritoneal cavity contained considerable serum, and its veins were engorged. The liver was enlarged, with distended veins. The kidneys were highly congested. The spleen was double its normal size and softened.

ABSCESS OF THE LIVER FOLLOWING ARRESTED MENSTRUAL DISCHARGE FROM EXPOSURE TO COLD; PYÆMIC ABSCESSES OF THE LUNGS AND SPLEEN; PERFORATION OF THE BOWEL; SEVERE HEART COMPLICATIONS; DEATH DURING THE SEVENTH WEEK.

Presented by DR. J. T. ESKRIDGE.

M. D., æt. 28 years, was a factory girl, whose father and two sisters had died of heart disease. She had had two attacks of inflammatory rheumatism, but had never complained of heart trouble. Her fatal illness began at night, by arrested menstrual flow, and severe cramping abdominal pains, coming on after exposure to cold during the previous afternoon. Fever and pain in the right lower side of the abdomen continued for three days, when she was able to work again for about a week. Jaundice began early, was well marked during the first three weeks, was slight afterwards, but lasted until her death. Her symptoms three weeks after the beginning of the attack, when admitted into St. Mary's Hospital in Dr. Hickman's ward, were: great prostration, emaciation, loss of appetite, pain in the right inguinal and lumbar regions, and irregularly recurring chilly sensations. Two weeks later, when first seen by Dr. Eskridge, the liver dulness extended nearly to the anterior superior process of the ilium, and the normal tympanitic note of the right inguinal region of the abdomen was replaced by one bordering on dulness. The tenderness was so great that neither fluctuation nor a tremor could be detected, if such existed. Great tympany soon developed and obscured the physical signs. A pyæmic condition, from which the patient perished in about two weeks, set in, attended by chills, fever, sweating, low temperature, and diarrhœa. A few days before death she passed considerable pus by the bowels. The surface temperature, taken over the chest and abdomen, showed the latter to be about two degrees warmer than the former, but all parts of the abdomen were of nearly the same temperature. Stenosis of the aortic and mitral orifices, with insufficiency of the valves of the latter, and a dilated hypertrophy of the left auricle and ventricle, were recognized during life. The post-mortem examination revealed the diagnosed lesions of the heart, and demonstrated the possibility of visible left auricular pulsation. The liver weighed eighty ounces (the right lobe being alone enlarged), and contained a large abscess surrounded by several smaller ones with which it was connected. The cæcum and its appendix were surrounded by about six ounces of pus, the latter being circumscribed by adhesions. Two openings were found in the black and gangrenous cæcum, one where its appendix had sloughed off, the other due to perforation of the bowel by the pus. The portion of the liver external to the hepatic abscess was firmly adherent to the abdominal wall, and from this point (about two inches above the crest of the ilium) the pus had burrowed its way and formed a sinus leading to the right inguinal region under Poupart's ligament. A direct communication between the liver abscess and the accumulation of pus surrounding the cæcum was seen.

DR. ESKRIDGE thought that the demonstration of the possibility of visible left auricular pulsation in the second left intercostal space, and of the occurrence of a functional murmur in the pulmonary artery without dilation of that vessel, was worthy of notice at present, as Dr. Broadbent had so recently advocated views almost diametrically opposite. Dr. Eskridge considered

mitral stenosis of not infrequent occurrence, and said, with care, the mitral presystolic murmur was not usually difficult to detect. The four physicians, including himself, present at the autopsy, then thought that the hepatic abscess was secondary to the inflammation and suppuration around the appendix and cæcum, but he, after carefully analyzing the clinical evidence and pathological lesions in favor of each condition, was satisfied that the case began as one of primary abscess of the liver following exposure to cold while the patient was menstruating.

The discussions on both these preceding specimens, which presented somewhat similar heart lesions, was now opened by DR. J. C. WILSON, who said that there was one point of special clinical interest in Dr. Eskridge's case, viz., the chronology of the lesions. He thought that the extensive multiple abscesses of the liver and lungs were secondary to the abscess around the caput coli. In some cases the determination of the primary source of the emboli was difficult, but in this case it was perfectly clear.

DR. BRUEN said that he would like to go on record among those who had observed auricular pulsation in cases of mitral obstruction, in which the stenosis was extreme.

DR. NANCREDE remarked that in his experience flexion of the thigh on the abdomen was an almost invariable early symptom in cases of perityphlitis, from which he would infer, that as this thigh flexion did not occur in Dr. Eskridge's case until within ten days of the fatal termination of the case, that the peri-cæcal abscess was secondary to that in the liver.

THE PRESIDENT said that he had been much impressed with the marked increase of the surface temperature in the neighborhood of the abdominal abscesses as compared with the general body temperature. As to the chronology of the various affections, he was inclined to believe that Dr. Wilson was correct.

DR. ESKRIDGE said, in reply to Dr. Wilson, that he could appreciate how the perityphlitis might be mistaken for the primary trouble, and the hepatic suppuration for the secondary; such a mistake (for he felt certain that the abscess of the liver was the primary affection) was made by all, including himself, who were present at the post-mortem examination. The pathological and clinical facts in favor of primary hepatic abscess were given at some length in his remarks in connection with the presentation of the specimens. In brief, the clinical features were as follows: Deep and early jaundice following exposure to cold, pain in the right side of the abdomen attended by fever and gastric irritability of a few days' duration; an intermission of a week, during which she was able to work, followed, after which gradually increasing weakness with dull, abdominal pain, attended by loss of flesh and appetite confined her to bed; ten days before death the development of intense tympany associated with flexion of the right thigh upon the abdomen. The hepatic suppuration was confined to the right side of the right lobe, all the smaller abscesses directly communicating with the large one, and the left lobe of the liver being apparently healthy.

TONGUE AND LARYNX FROM A CASE OF ELEPHANTIASIS GRÆCORUM.

Presented by DR. A. C. W. BEECHER.

The case from which these specimens were removed was reported in the *Photographic Review of Medicine and Surgery*, No. 6, vol. i., August 1871. Mr.——, æt. 26 years, born in Cuba, of Spanish parents, married. His father was living when the patient died in 1872; the mother died when he was an infant. He was wet-nursed by a colored house-servant, who was unmarried, but had had several children by different individuals. She was healthy as far as known, with the exception of sores upon her feet. He had none of the diseases of early life except measles and mumps. His health was good up to 15 years of age, when superficial yellowish-pink spots appeared upon his body, accompanied by neither pain nor itching. They remained about one year, and disappeared during a voyage to Spain. While there he was attacked with neuralgia of the little fingers, extending along the course of the ulnar nerve to the elbow, which was relieved, and he returned to the West Indies. Six months after his return he experienced a second attack, which lasted for one month. In 1862 he came to this country to study, and after one year became the subject of repeated catarrhs, chiefly affecting the throat. Itching of both forearms and legs soon after developed. In 1866, œdema of the hands and feet, which did not extend beyond the wrist or ankle, set in, producing a sensation of stiffness of the fingers and toes. Blebs then suddenly appeared in varying size upon the dorsum of the hands and fingers, extending over the whole length of the latter. At times a sharp pain in the hands and fingers, arousing him from sleep, would herald one of these bullous attacks. The bullæ contained a whitish opaque fluid, and when burst were succeeded by dark-brown scabs, transversely cracked and fissured over the finger joints. Under these crusts were excavated ulcers. The finger-tips and the ends of the toes presented similar ulcers, over which the nails grew, and these latter being brittle broke off when long. Next frequent hemorrhages from the nose, coming on while laughing, or in mental or physical excitement, were noted. The nose became tender, was much swollen, and discharged moderately offensive pus, and the bridge of the nose began to sink, gradually assuming its present appearance (a photograph was here shown). A year after the hands were attacked the face became similarly affected, the ulcers on healing leaving distinct cicatrices. The eruption never entirely ceased, new bullæ and ulcers forming while others healed. There was marked emaciation. The hair, which was everywhere scanty, was absent in many spots on the body, and the skin was of a dusky hue. The muscles of the arms were much wasted, and the skin presented small white cicatrices. Over both patellæ and olecranon processes, large, hard, firm, reddish nodules were seen. The hands were much deformed, with wasted, contracted fingers, having numerous small hard tubercles scattered beneath the skin of the dorsa of the hands. Numerous ulcers, mostly covered with irregular black scabs, covered the back of the fingers. A markedly varicose condition of the veins near the wrist was observed. The hair of the head was normal in quantity, but was hard and harsh, while there was total loss of eyelashes and eyebrows, and the beard was scanty. There was a large hard tubercle over one frontal boss, near which was an old ulcer. The nose was much sunken, there was an ulcer over the right zygoma covered by a black rupia-like scab; the face was marked with scars, and the ears were likewise deformed with traces of numerous cicatrices. Many of the teeth were decayed and broken off close to the gums. The tongue was much thickened with greatly enlarged papillæ. The velum palati was almost gone from ulceration, and yellowish-white tubercles existed in the pillars of the fauces. The larynx was much contracted by thickening of its mucous membrane. The epiglottis was about twice its normal thickness and had several well-marked tubercles upon it. The voice was much impaired, weak, and had a peculiar husky sound. There were deep sloughing ulcers over each tendo Achillis. Tactile sense was very much impaired, as in the dorsum of the hands, where the sense of touch was almost absent, and what was recognized was referred to some point in the neigh-

borhood of the point of contact. The sense of pain was almost entirely absent in the hands and forearms, becoming more marked as the body is approached; a pin passed through the pulp of the middle finger gave absolutely no pain. The difference between very hot water and that of an ordinary temperature was readily perceived; moreover, there was general increased cutaneous sensibility to temperature changes. Taste and smell were somewhat impaired. Very slight anæsthesia of the trunk exists. Sight was good, although prolonged use of the eyes was painful. The general health of the patient was fair. There seemed to be no trace of venereal disease. Sexual power was absent. Frequent neuralgic pains of the legs and arms were complained of. The atrophy of the hands, feet, fingers, and toes was appreciable from month to month. The cornea next became ulcerated, the conjunctival surfaces became adherent, and almost total blindness ensued. Swallowing was almost impossible towards the last, owing to the pain produced by the thoat ulcers and because from imperfect closure of the rima glottidis fragments of food lodged in the larynx, producing violent and exhaustive coughing. Respiration was also so much impeded that he died October 29, 1872, partly from dyspnœa, partly from starvation. Up to death he suffered intensely.

Autopsy.—Rigor mortis well marked; great emaciation of the entire body noted. The surface of the tongue was fissured, the papillæ enlarged, with the remains of tubercles well marked toward its base. The epiglottis was curved on its long diameter, thickened, and stiff, with its upper margin eroded by a large ulcer. A deep ulcer was situated in the mucous membrane near the apex of the left greater cornu of the hyoid bone. Narrowing, from thickening of tissues, involved the trachea at its upper part, and produced such a stenosis of the chink of the glottis that an ordinary quill could not be passed between the vocal chords. Upon section of both ulnar nerves near the elbow, extensive degeneration was detected. This case was examined both by Dr. Duhring and Dr. R. Bartholow—the latter making a laryngoscopic examination—who both considered it to be of the mixed variety, viz., tubercular and anæsthetic leprosy. The case is interesting both from its rarity and the possibility of other cases being brought here from California and New Brunswick, in both of which places it is not uncommon. Again, its resemblance to syphilis at first led him into error, although Dr. Beecher said that he had recognized something strange about the disease. The late Dr. Maury saw the case with me, and had no doubt of its syphilitic nature until Dr. Duhring's examination of the case convinced him that it was really leprous. Erasmus Wilson says: The resemblance to secondary syphilis is so striking that an error is certain, excepting on the part of those who have had an opportunity of seeing and observing leprosy.

DR. WILSON asked whether the family history had been investigated.

DR. BEECHER replied that he had carefully questioned all concerned, but had ascertained nothing special, except that when such cases occurred in wealthy families the fact was always hushed-up.

DR. WILSON said that in this connection he would call the attention of members to a very able article in the last issue of *The American Journal of the Medical Sciences*, where the writer took the view that leprosy was contagious, maintaining that it should be investigated where it was of rare and recent occurrence. Dr. Wilson also referred to its occurrence among recent immigrants in certain of our northwestern States.

DR. CARL SEILER said that Dr. Beecher had asked him to examine the specimen of the larynx and tongue of the case of elephantiasis. The dorsum of the tongue was deeply furred and the papillæ appeared enlarged. The epiglottis was thickened, very stiff, and rolled on its long axis like a leaf. On its upper free margin was a crescentic ulcer with raised edges, and numerous small roundish ulcers were scattered over the laryngeal surface of the epiglottis. Extensive ulceration of both ventricular bands and vocal cords existed, so that the opening of the ventricles was almost entirely occluded. The ulcers were symmetrical and most marked towards the anterior insertion of the vocal cords. About a quarter of an inch below the cords was a cicatricial band projecting from the sides of the subglottic cavity, and leaving an elliptical opening through which a crow-quill could hardly be passed. Below this obstruction the mucous membrane of the subglottic cavity was studded with small round ulcers, while the trachea seemed healthy. No further lesions could be detected by the naked eye, although, doubtless, such had existed, but had been obscured owing to long preservation in alcohol. Dr. Seiler regretted the absence of the records of the laryngoscopic examinations made before the patient's death; still the lesions seen in the specimen would explain the symptoms of dyspnœa, aphonia, and dysphagia, and it was astonishing how the patient could have respired at all through the narrow opening left by the cicatricial tissue below the glottis. The chief interest, however, centred in the great similarity of the lesions in this unique case with those found in syphilis and lupus of the larynx. He had seen ulcerations in syphilitic laryngitis almost identical in shape and location with those seen in the specimen, and he remembered having seen two or three specimens of lupus of the larynx, when in Vienna, which bore a strong resemblance to syphilis. Lupus and leprosy of the larynx could not be diagnosed from one another by laryngoscopic examination, but other signs and symptoms outside of the larynx had to aid in the diagnosis. Thus in a syphilitic laryngitis there were always sharply defined bands of a deep red color on the free margin of the velum palati. In lupus, affections of the skin of some part of the body always preceeded, co-existed with, or shortly followed the manifestations of the disease in the larynx, while in leprosy the larynx was usually attacked later in the disease when other portions of the body clearly showed marks of the pest.

DR. LITTLE remarked that, having conversed with Dr. F. H. Enders, who had seen a great many cases of leprosy in the Sandwich Islands, he had been interested to note that the eyelids were affected in the early stages, ectropion resulting, and the conjunctiva and cornea, or even the whole eyeball, becoming involved. The affection of the eyelids is sometimes the first symptom, or occurs during the first or second year of the disease. The lids were involved in the case described, and the eyeballs subsequently.

CINCINNATI.

(*From our Special Correspondent.*)

SMALLPOX IN CINCINNATI.—A recent issue of an Eastern daily paper contains a statement that "the ravages of smallpox in Cincinnati have been withheld from the public," and that "since August 24 there have been four thousand cases, of which fifteen hundred were fatal." The law requiring the registration of infectious diseases is strictly enforced in this city, so that your correspondent experienced no difficulty in obtaining the correct figures, which completely refute the above statement. The records of our Health Office show that since the first appearance of the disease, in January, 1881, a period of twenty-two months, only

4,000 cases have occurred, and of these, 1248 proved fatal. In the month of August, this year, there were 90 deaths from smallpox; in September 70, and in October 36. The disease has rapidly decreased, until, at the present date, there are only 20 cases in this city of 300,000 inhabitants, and these are confined to the German districts, where the greatest difficulty is encountered by the authorities in their efforts to secure general vaccination. In these portions of the city there will, of course, be more or less smallpox during the coming winter, but all attempts to magnify this small number into a general epidemic are unjust to the city, the general health of which is quite good. Your readers should not be misled by the frequent reference in the daily and medical press of this city to the bad character of our Board of Health. It is at present an unusually incompetent collection of ward politicians, and deserves to be abolished; but its members have interested themselves chiefly in the management of the funds of the board, and the distribution of minor offices, fortunately leaving the control of smallpox affairs in the hands of the Health Officer, who has done all that could be reasonably expected of him.

CHICAGO.

(*From our Special Correspondent.*)

THE MEDICAL SCHOOLS.—The reputation of our city as a medical centre of instruction is fully maintained this year by the number of students, which is between 800 and 900, distributed amongst the four regular medical schools. The Woman's Medical College, as far as we know, the largest in the West, has the respectable number of 75 matriculants. Rush College, the oldest, claims the lion's share, with nearly 500 students, while the Chicago Medical College and the College of Physicians and Surgeons each have about 140.

The College of Physicians and Surgeons, though only opened this autumn, owes its fair start in numbers in no slight extent to the reduced fees, which are but half of those of the other institutions. But it has to contend with unfavorable auspices from the onset. Built near the County Hospital in the hope of using it for clinical purposes, the prospect has been somewhat marred by the action of the County Commissioners, who have control of the Medical Staff of the County Hospital. After long efforts the new school succeeded in being represented on the staff by one member of its faculty. However, other restrictions on the part of the County Board have rather diminished the availibility of that hospital for clinical demonstration.

BOGUS DIPLOMAS.—A new medical hatching machine has been discovered by the State Board of Health, who refused to admit to practice a certain Dr. Thompson, whose diploma was signed by the President of the "Bellevue Medical College of the State of Massachusetts," of Boston. Bogus letters were sent to the alleged Dean, Dr. Rufus Noyes King, in which the correspondent, with a strenuous attempt at illiteracy and knavery, asked for information as regards the terms of graduation in that school. The *bona fide* answer is fully up to the questioner's epistle, in both the above-mentioned qualities, and revealed a diploma factory in the Buchanan style, in which instruction is given (if desired?) with special reference to diagnosis, treatment, and doctoral conduct. To satisfy all possible demands, the corps of instructors is said to consist of representatives of the two medical schools. Dr. Thompson is as yet without license.

THE HEALTH OF THE CITY was seriously threatened by a fresh outbreak of smallpox in October, traceable to a few concealed cases. By strict vigilance, however, the Board of Health has become master of the situation, and very few cases of the disease have made their appearance since. Scarlet fever was also alarmingly prevalent, though of a mild type. This likewise has diminished, and the mortality reports now show a better sanitary condition of the city than has existed for several years.

ANN ARBOR, MICH.

(*From our Special Correspondent.*)

THE CHARGES AGAINST PROF. FROTHINGHAM.—A matter of more than usual interest has attracted the attention of the medical profession and the laity of Michigan. Briefly it became public through a written complaint made to the President of Michigan University, at Ann Arbor, by a student of the medical department, against Dr. G. E. Frothingham, Professor of Materia Medica, Therapeutics, and Ophthalmology and Otology. The complaint against the Professor was that he took the time of the students in denouncing religion, churches, and ministers. The student who made it has for years been a missionary on the Pacific coast, and is about forty-five years old. For a year and a half he has been at the medical department of the University. Prof. Frothingham denied the charge, and in turn arraigned Mr. Morgan, the complaining student, before the Medical Faculty as having in his complaining letter to the President been false in both spirit and letter. The Faculty met, heard both the accuser and accused, and witnesses on both sides, and decided that the charges of Prof. Frothingham against Mr. Morgan were not sustained. Five of the Faculty were present at the meeting which rendered this decision. The names of the majority are understood to be Professors Dunster, Langley, and Herdman; the names of the minority are Profs. Palmer and Sewall. Profs. Ford, Maclean, and Prescott were not present.

Prof. Frothingham now announced that if the matter was to be left in this way he would resign. Prof. Maclean said that he would do likewise. The Medical Faculty then held another meeting in which they passed resolutions to the effect that 1. Mr. Morgan in entering a complaint against Prof. Frothingham violated one of the University laws and stepped beyond his privileges; 2. Mr. Morgan, in his letter to President Angell exaggerated and misrepresented many important points in his charge against Prof. Frothingham; 3. The Faculty in voting upon these resolutions does not wish to impeach the veracity of any student or witness concerned.

In view of this action of the Faculty Prof. Frothingham has concluded not to hand in his resignation at present, and of course Prof. Maclean will do likewise.

Such in brief is an outline of this quite remarkable transaction. It is possible that we have not yet heard the end of it.

VIENNA.

(*From our Special Correspondent.*)

SYNTHESIS OF URIC ACID.—An important discovery in physiological chemistry has recently been made in the chemical laboratory of Prof. E. Ludwig, by Dr. Horbaczeoski.

Prof. E. Ludwig announced the discovery for the first time in the Society of Physicians, upon the evening of November 3d. Dr. Horbaczeoski heated urea and glycocol very quickly up to 230° C., and then allowed the two substances to fuse until evolution of gas ceased. A brown mass resulted, from which uric acid was separated by a very complicated process.

Uric acid, as thus obtained, presents under the microscope the characteristic whet-stone shaped crystals, and when tested chemically reacts in a perfectly satisfactory manner.

This discovery of Dr. Horbaczeoski is the first synthesis in physiological chemistry that has ever been

made. It will be remembered that in 1828 Wöhler succeeded in the formation of uric acid from ammonium cyanate. This discovery was not a synthesis, in the true meaning of the word, inasmuch as a more complex combination of elements was not built up from simpler combinations. Then, again, Dr. Horbaczeoski formed uric acid out of urea and glycocol, two substances found normally in the living human body.

Since the evolution of the formula for uric acid, $C_5H_4N_4O_3$, by Wöhler and Liebig, in 1828, the problem which the young investigator in Vienna has solved has been the occasion of infinite toil in all chemical laboratories. Mulder, Bayer, and Stretchen have worked in vain upon the subject. Bayer's pseudo-uric acid, produced by the reaction of cyanamide upon alloxantin, reacts under the murexide test, but fails in other characteristics. Strechen's experiments with glycocol certainly pointed the way to the discovery.

Prof. Bayer has telegraphed his congratulations from Munich. While the significance of this discovery is great as an absolute fact in physiological chemistry and biology, it will probably lead to important results in clinical medicine and therapeutics.

Prof. Carl Braun Challenged by an American Physician to Fight a Duel!—A popular medical journal appeared upon last Tuesday with a very sensational account of a quarrel between Prof. Braun and an American physician, who has been engaged, for some time, in the special study of obstetrics.

According to the story, the American, after breaking the arm of a child, with dorsal displacement of the right arm, in a footling presentation, absented himself from the clinic, fearing to encounter the irate Professor's very excellent German or equally vile English. Prof. Braun's remarks were reported by a colleague, who did not understand German, to the operator. Prof. Braun applied the term "feigheit" (*i. e.*, cowardice) to the young man's conduct in a perfectly playful manner, and only desired to impress upon the young man's mind that he had not necessarily been guilty of an awkard operation.

The American thoroughbred ("Amerikaner vollblut") became highly incensed, and in company with a comrade repaired to Prof. Braun's residence, in London Gasse, charged him with the insult, demanded an apology before the college or a duel with pistols at ten paces at Schön-Brun.

Professor Braun endeavored to calm the hot-headed youth, refused to make a public apology, and stated that, whatever American social laws might be, it was not a custom in Austria for a professor to fight with his students. Not at all satisfied with the result of this interview, the American betook himself to Judge Taft, the American Minister, and unburdened his tale of woe. After mature reflection, Judge Taft concluded that the Professor was not altogether in the wrong, thought the occurrence was not a sufficient *casus belli* between America and Austria, and begged the American to let the matter drop.

All the Vienna daily papers caught up the item at once, and the affair has been town-talk for a week. The North German papers have heard of the matter, also, and our American friend has achieved, within a very short time, a great notoriety.

Your correspondent knows the American physician and Professor Braun, and from the lips of both, is able to assert that the whole story is a fabrication, a typical example of Teutonic wit.

Farewell Lecture of Dr. O. W. Holmes.—Dr. Holmes delivered his farewell lecture before the medical class at Harvard, on Tuesday, November 28th. One o'clock, the hour for the anatomical lecture, found the amphitheatre packed with students of all classes. Among them many gray-haired practitioners were assembled to hear their old teacher give his last lecture. The Medical Faculty occupied seats within the rail. In front of the desk was a large plaque of flowers about three feet in diameter. The entrance of the doctor was marked by the rising of the students, and as their applause ceased, Mr. Washburne, on behalf of the class, presented him in behalf of his last class with a beautiful loving-cup, inscribed with a quotation from one of his own poems. Mr. Washburne said: Dr. Holmes, it is with deep regret that we come to this farewell. We had hoped, when we entered upon our course to be permitted to listen to your lectures through the year. But we are thankful that we have enjoyed this privilege at all. Desiring to express our regard in some form more tangible than mere words, we beg you to accept this gift. As you may look at it, we hope you will sometimes remember us as we shall always remember you. In the language of the inscription, "Love bless thee, Joy crown thee, God speed thy career." A photographer was present, and while he was taking the scene the doctor had time to overcome his emotion.

There was three times in a man's life, he said, when he might properly consider himself the centre of attraction—at his christening, at his marriage, at his own funeral. This, the beginning of his thirty-sixth course of lectures on anatomy, was the end of his connection with the school. For about half of this time he had also taught physiology, but with the growth of the science he had gladly given it over to form a new department. It was a good thing for a college to get rid of her old men. Their ideas were antiquated and the college had better let them go. He had held his office so long because he taught a subject which could never become antiquated. In his lifetime it had received very few important additions. He had begun the study of law in his youth as an experiment, but for various reasons had turned his attention to medicine. While in the law school he had engaged with some friends in publishing a paper and for the first time saw himself in print. From the printer's type he had contracted the disease of authors, head-poisoning, which he had never quite got rid of. The doctor finished with some practical remarks on the way in which the science was tending.

Annual Report of the National Board of Health.—The fourth annual report of the National Board of Health was transmitted to the Secretary of the Treasury on the 29th ult. Among the papers promised, as appendices to the report, are the details of Prof. Mallet's work on "Water Analysis," an abstract of which has already appeared as a supplement to the now suspended *Bulletin;* Philbrick and Bowditch on the "Siphonage of Traps," Bowditch's "Survey of Summer Resorts," Wood and Formad "On the Relations of Diphtheria to other Septic Diseases;" a second paper by Profs. Rumpelly and Smyth on "The Filtering Capacity of Soils," and the report of a Committee on the Registration of Vital Statistics, are also appended, and will be looked for by those interested in sanitary matters with considerable interest. In the last-mentioned paper the position is taken that there need be no difficulty in procuring in this country as complete a registration as is obtained in any other, and the suggestion is made that the State registering officers furnish the data to the general government, which, on its part, should agree to pay part of the expense of collecting them. The Board approves of this suggestion of the Committee, and recommends a special appropriation by Congress for this purpose.

The relations of the National Board of Health to maritime quarantine are clearly explained.

The law of June 2, 1879, usually referred to as the *quarantine law*, imposes certain duties on the Board in connection with quarantine, but conveys no quarantine powers. These powers are vested in the State and municipal authorities, and the duty of the Board is to aid these authorities in the execution of their rules and regulations for the prevention of the introduction of contagious diseases. Hence, the establishment of the Shir sland, Sapelo Sound, and Elizabeth River Stations as aids to the local authorities on the Gulf and Atlantic coasts. That a station of similar character is required near Galveston, Texas, seems manifest from the events of the past summer, but no recommendation is made to this effect, probably because this has already been done in previous reports. In referring to the history of a steamer which entered San Francisco harbor with smallpox among her Chinese passengers, the report remarks: "This particular case has reference only to smallpox, but when the devastation effected by cholera in Japan since April last, is considered in connection with the intercourse between Yokohama and San Francisco, and the railroad facilities between the latter port and the whole of the United States, the subject assumes a larger proportion, and in the event of inability in the part of State or municipal authorities to establish a local quarantine, a recommendation by this Board for the establishment of a refuge station on the Pacific coast seems called for by the general interests of the country."

The report urges that bills of health should be required of all vessels coming to the United States. This would have the beneficial effect of causing special attention to be paid to the condition of vessels at their ports of departure, in order that clean bills of health might be obtained by them, and would thus by so much lessen the number of vessels to be treated in the refuge stations and the local quarantine, and the chances of the importation of exotic contagious diseases. As the law stands, at present, a penalty is imposed upon vessels which enter upon our ports without bills of health, but this law cannot be enforced, as in the first place it throws upon this government the burden of proving the port of departure an infected one, and in the second, the law contains a proviso requiring its official promulgation in the ports of departure, and this official promulgation was not permitted by the Cuban authorities.

The inter-State inspection service on the Mississippi River is reported as having worked well during the past as during previous summers, in giving security to the people of the valley above New Orleans against the propagation of yellow fever from unsuspected or unreported cases in that city. Travel and traffic by river and railroad continued unchecked under the condition imposed by the States of the valley to wit: the certificate of a National Health Board inspector, that the vessel or train was free from the infection of yellow fever or from any reasonable suspicion of such infection.

The immigrant inspections which were instituted in June last, appear to come under the headings of both *maritime* and *inter-State quarantine*, for they involve inspections at the ports of entry, such as New York, Philadelphia, Baltimore, and Port Huron, as well as later inspections at certain large distributing railroad centres, such as Chicago, St. Louis, etc. These interior inspecting stations are needful, because the disease, smallpox, against the importation of which the inspections were instituted, has a period of latency which permits an immigrant who has been exposed at an European port before sailing to pass the quarantine inspector at the port of entry, and proceed undetected on his westward journey. The inspectors do not simply look out for smallpox cases, and isolate, disinfect, and vaccinate in the event of their detection, but they examine all immigrants as to their protection by vaccination or previous attack, and if this is found to be unsatisfactory, protection is afforded by a fresh operation. The steamship managers and surgeons have coöperated with this service by having their immigrants inspected and vaccinated during the ocean passage. Boston has established inspections in accord with the work of the general service, but the Board has not been required to pay for them.

The suspension of the *Bulletin* is regretted, and its restoration recommended.

A few words only are given to the epidemics at Pensacola and Brownsville. It is noted in connection with the latter, and the attention of Congress is invited to the fact "testified to by those who are cognizant of the epidemiology of yellow fever in that section, that while an inspector of this Board was on duty at the mouth of the Rio Grande, the fever was excluded, although the conditions predisposing to invasion were as imminent during that period as they were at the time when the disease effected its entrance."

The report then defends the Board against the charges which have been made, that it has exceeded its authority. It shows that all the work which has been done comes directly under the provisions of the Acts of March 3 and June 2, 1879. It closes with an itemized, tabular statement of the expenditures since the organization of the Board, which shows that the charge of extravagance is equally unfounded. No part of the contingent fund of $100,000 has ever been used by the Board. The first use of that fund was made by Surgeon-General Hamilton, at Brownsville.

The estimates for the continuance of the work of the Board, amount to $150,000. A contingent fund of $100,000, to be used in case of an epidemic, is also recommended.

DIPHTHERIA IN PHILADELPHIA.—The latest information with regard to the prevalence of diphtheria in Philadelphia shows that this disease is on the increase, and more generally distributed throughout the city. The decrease in the deaths noticed in our last issue was only an apparent abatement of the epidemic.

The number of deaths reported for the week ending December 2d was 42, an increase of 13 over the number for the preceding week, and 3 more than the greatest number recorded in any previous week during the year.

Deaths are reported in 20 out of a total of 31 wards. In the 23d Ward, or Frankford, with a population of 26,522, there were 7 deaths, against 4 in the preceding week. In this outlying district the disease has been most persistent from the start, and there appears to be no indication of its abatement. Quite a number of cases have occurred among the employés of the United States Arsenal, requiring the most rigorous measures to prevent its spread. The 24th Ward, also a semi-rural district, and widely separated from Frankford, also shows a marked increase in the number of cases and deaths. There was 5 deaths reported, against one in the preceding week.

The health officer reports 165 new cases for the week ending December 5th. These are unequally distributed among all the wards, with the exception of the 14th, which reports no cases during the week. This shows a very general prevalence of the disease, though, as might be expected, in some wards it has gained a much stronger foothold than in others. There are 21 new cases reported in the 24th Ward; 15 in the 29th; 12 in the 31st; 11 in the 20th; and 9 each in the 1st, 12th, 19th, 23d, and 28th Wards.

The total number of deaths for the year to Decem-

ber 3d, is 801. Of this number, 174 occurred in the first quarter; 163 in the second; 215 in the third; and 249 in the first nine weeks of the fourth quarter. The indications are that the last quarter of this year will show a far greater mortality from this cause than has ever occurred in the same period of time.

THE COMPENSATION OF PRESIDENT GARFIELD'S SURGEONS.—The claims allowed by the Garfield Board of Audit have just been made public. The physicians get $27,500. Of this amount Dr. D. W. Bliss gets $6,500; Dr. D. Hayes Agnew, $5,000; Dr. Frank H. Hamilton, $5,000; Dr. Robert Reyburn, $4,000; Dr. Silas H. Boynton, $4,000, and Dr. Susan A. Edson. $3,000. The amount awarded for services and supplies was $5,929.93. The items range from $13 for express hire to $1,500 for the Central Railroad of New Jersey. Under head of extra services by government employés the items range from $15 to $200, with a total of $5,440. The grand total is $38,869.93. The total appropriation to pay claims against the Garfield estate was $57,500, of which amount $35,500 was specially appropriated for physicians and medical attendance. It will be seen that the allowances for the physicians and medical attendance are $8,000 less than the amount appropriated, and that the allowances for outside claims are about $11,000 less than the amount available, making a total balance of nearly $19,000 out of the entire appropriation of $57,500.

A FOREIGN HONOR TO DR. PARVIN.—The Edinburgh Obstetrical Society has elected DR. THEOPHILUS PARVIN an honorary member.

LIGATURE OF THE EXTERNAL ILIAC ARTERY FOR FEMORAL ANEURISM IN A CHILD.—The English journals announce the occurrence, at the East London Hospital for Children, of a case of femoral aneurism in a boy twelve and a half years old, in whom the external iliac was tied on November 10; the case has as yet progressed favorably; the subsequent history is promised.

THE "FAITH CURE" ESTABLISHMENT OF BUFFALO has been broken up by reason of lack of funds. The inference is unavoidable that the power of faith may be equal to such a trivial work as the cure of disease, but is not equal to the more arduous task of raising a sufficient supply of money to keep the institution in operation.

A DIRECTORY FOR NURSES IN TORONTO has been established under the auspices of the Toronto Medical Society.

PROF. VIRCHOW'S HEALTH.—Our latest German exchanges announce a steady improvement in Prof. Virchow's health. He has been suffering for some time from an attack of acute nephritis, complicated by rheumatic neuralgia, and commencing with slight hemorrhage. He is now free from fever, and the amount of albumen in his urine is steadily declining.

JEFFERSON MEDICAL COLLEGE.—The trustees of Jefferson Medical College, Philadelphia, have elected DR. J. SOLIS COHEN Honorary Professor of Laryngology.

SIR THOMAS WATSON.—The latest English journals report that Sir Thomas Watson has been gradually growing weaker, and his sufferings have been increasing.

A MALPRACTICE TRIAL IN MICHIGAN.—In the suit of Wood *vs.* Barker, Mr. Justice Campbell, the other justices concurring, of the Supreme Court, has just filed the following decision.

Plaintiff, who is a surgeon, sued defendant on his promise to pay for professional services rendered to one Murray, who had been injured by a blast, so that both legs were badly crushed below the knee. Plaintiff was called in as counsel to aid the attending surgeon Dr. Harding, shortly after the accident at Sault Ste. Marie. The left leg was amputated, and they were both of opinion that amputation of the other was expedient, by reason of the extensive comminuted fracture of the bones and laceration involving injury to an artery, to prevent extreme danger of death. The opposition of Murray to this prevented the amputation and the limb was ultimately saved but not entirely restored to its original condition. Some time after the plaintiff had ceased his visits and while the case was in the hands of Dr. Harding, aided by a nurse, Dr. Jessop, of Mackinaw, came over and was employed to treat the patient in connection with Dr. Harding. The only medical testimony in the case was given by plaintiff and Dr. Harding. Dr. Jessop was not sworn. The employment by defendant seems to have been shown, and the questions on which the controversy appears to have turned were the value of the services and the propriety of the treatment.

It is to be observed that there is no conflict of testimony whatever in regard to the fact of the work and attendance of plaintiff, and no testimony which did not leave a considerable sum due him if those services were properly rendered. The court in charging the jury told them in substance that they were at liberty, if not satisfied with the testimony of the experts, to use their own judgment on the question of value. They were also instructed that if plaintiff's course was unskilful, they might reduce the fees accordingly, as in their judgment should be deemed proper. They gave plaintiff nothing. There can be no presumption of law concerning the value of a surgeon's services and there is no presumption that a jury can ascertain it without testimony of some kind, from persons knowing something about such value. As already suggested there was positive testimony of value not discredited, and, in the case of Dr. Harding, given by a disinterested witness called for important purposes by the defendant himself. We can see no sufficient reason for the suggestion that all of this testimony might be disregarded, and there is no rule which would allow the jury to entirely ignore the testimony, and at the same time to form an independent conclusion without testimony upon a matter which required a proof beyond their conjecture or their opinion. We do not say that the value of a physician's services at a given time and place may not be known to other persons than physicians, if they have been in a position to learn the customary or proper rates. But there is no legal presumption and no reasonable probability that all jurymen have this knowledge. And there can be no safety to any one if juries are to use their own unguided views on such matters.

Neither was there any evidence which would justify the jury in reducing the otherwise appropriate compensation on the ground that plaintiff's treatment was improper. There was no such evidence. The fact that the injured limbs were slow in healing and imperfectly healed at last does not necessarily show that the treatment was improper. The injuries as described were of a very aggravated nature, and beyond any ordinary fracture, the limbs being bruised and badly lacerated, the bones crushed, and an artery torn. Both medical witnesses were of opinion that there was danger in leaving the right leg on. There is nothing to show that the course taken under plaintiff's oversight was not the proper one, and nothing to show that when he left the case in the hands of the regular

surgeon and nurse, anything necessary had been omitted or anything done out of the way. On the contrary, not only the plaintiff, but Dr. Harding gave positive testimony the other way. There is nothing to show that plaintiff did not possess and use competent skill. The fact that some time later Dr. Jessop made some change in the management of the remaining limb had no tendency to show that the previous treatment was not proper at the time, and no one testifies it was not. Dr. Harding's testimony indicates entire harmony of views, and Dr. Jessop is not produced to contradict him. No other medical testimony is offered to show any failure of skill or any mistake in the treatment.

Where all the testimony in the case is in favor of the treatment pursued, and the question is one of medical skill which can only be tested by those familiar with such matters, it was error to let the jury draw adverse conclusions, which could only be based on their unprofessional notions of how such injuries should be treated. The fact that Murray survived is not evidence that his case was not desperate in appearance or in fact, and the fact that his limb is not restored to perfect soundness is no proof that he has been maltreated. The jury could not rightly be allowed to find malpractice without testimony from persons who were qualified to give opinions on the methods of treatment.

The judgment must be reversed with costs, and a new trial granted.

DR. C. R. AGNEW ON THE NEW CODE.—DR. AGNEW, of New York, has addressed a letter to the *Louisville Medical News* in response to its strictures on the new Code. He says "Much had been done, it is true, in earlier days by our profession to protect the public, and the old Code had in its day been of great value as one of the few safeguards. But when the population of the country began to grow with marvellous rapidity, and heterogeneous social elements to pour in upon every community, the medical profession with its proscriptive code could do very little that was effective to oppose the tide of charlatanry and medical incompetency. It could do much in its medical schools to advance the standard of education, and thus supply more and better physicians; but the agency of the State came to be more essential in mitigating the evils of quackery and medical incompetency, and in providing and enforcing sanitary laws.

"I have thus, in a few words, hinted at what I believe to be the ruling motives which influenced our State Society to act. And furthermore, many of its members believed that the tone of the profession would be vastly improved if liberty of conscience and judgment were fully accorded to the members of the only one of the three learned professions still not fully in possession of it. And this idea was very influential in forming the new Code and in its adoption by the Society.

"You may ask what do we expect will follow practice under our new Code? Less acrimonious criticism of legally qualified doctors; more careful study of those things which will raise the standard of medical education and character; more activity in those fields of State and national politics which include the great sanitary interests of the people; more vigilance in pursuing medical outlaws; more diffusion of light to educate the people, to lessen irrational credulity, and to reveal the tricks of incompetent or dishonest medical practitioners. It will force us, as a profession, to combine with legislators to protect the people, and become a greater factor in social and sanitary questions."

Dr. Agnew unfortunately fails to point out how the new Code is going to influence these reforms, and this last defence is not likely to make a single convert. In an editorial comment on the letter the *Louisville Medical News* says: "We imagine the thoughtful reader will find no little difficulty in following Dr. Agnew through the premises which seem to have led him to the conclusion that to protect the public from quackery the medical profession should take the quacks into fellowship, and thus publicly recognize them as physicians worthy of confidence and affiliation. We can conceive no proposition more absurd. And again, our metropolitan *confrère*, admitting that the Code of Ethics of the American Medical Association has, "in its day," been of great value as a safeguard to protect the public from quackery, claims that now the population of the country has so increased that it has become ineffective. It must be remembered that the question under consideration is one of ethics, and it must be conceded that what is right in a country of two millions is equally right and just in a population of fifty millions. The great principles of ethics and morals are immutable, and are altered neither by longitude nor latitude, nor by growth of a population in heterogeneous elements. Our correspondent's explanation of the motives of the New York State Medical Society which led to a departure from the Code of Ethics will scarcely satisfy the thoughtful reader of his letter."

CHOLERA PROSPECTS.—DR. PROUST, in a note on the present situation of Southern Europe, with regard to cholera, points out that to pass from India to Europe cholera has heretofore followed two routes. The first in 1823, 1830, and 1847, was the land route from Afghanistan, Persia, and the Caspian Sea. The second is the sea route followed by the epidemic of 1865, viz., by the Red Sea and through Egypt. At the present time the land route does not appear to present any dangers for Europe, but the case is somewhat different as regards the other. Last year the presence of cholera among pilgrims at Mecca exposed Europe to great dangers, and the Egyptian troubles gave rise to very considerable alarm, owing to the proposed reinforcement of the Egyptian army by troops coming from India; this led to the French Government calling the attention of the English foreign office to the desirability of taking special measures to keep out cholera from the Red Sea.

At present all fears of importation by troops coming from India are dissipated. There has not been any cholera in Egypt nor anything resembling it, but cholera exists in many points in the extreme east, in Japan, in the Philippine Islands, in Java, in Sumatra, and in India. This, however, has been the usual condition for the last twenty years; the real danger is in the Red Sea, and is due at present to the Mecca pilgrimage. Cholera, in fact, has appeared on the ship Hesperia from Bombay, with a cargo of five hundred pilgrims. This ship was given a clean bill of health, on the ground that cholera was not epidemic at Bombay, there being only some isolated cases there. This, Dr. Proust insists, was a grave error, the danger of the importation of cholera having no relation to the quantity of the disease at the port of the departure, but rather to the character of the emigrants.—*Sanitary Engineer*, Nov. 16, 1882.

IMMIGRANT INSPECTION SERVICE IN THE WESTERN DISTRICT DURING OCTOBER.—From the monthly report of DR. J. H. RAUCH, the Supervising Inspector of the National Board of Health Immigrant Inspection Service, we learn that of the immigrants arriving in the district during the month, 16,473 were inspected by the Assistant Inspectors, who found 3,353, or about one-fifth of the whole number, whom they deemed it desirable to vaccinate or revaccinate. Among these were 350 who had never been vaccinated at all, and these included an unusually large number of adults.

Of the total number (16,473) of immigrants inspected

in this district during the month, 4,728, or nearly 30 per cent., were susceptible on landing; but 1,364 of these were vaccinated or revaccinated by Eastern inspectors before arriving in the Western District. If this proportion holds good with the total number of immigrants arriving in the country, then only a little over one-third of the susceptible are properly protected in the Eastern inspection districts. This may be due to the reduction in the number of inspectors last month, but it is also probable that the inspectors pay more attention to the immigrants who settle down in their respective districts, and only vaccinate as many of those going beyond their boundaries as they find time and opportunity for.

There have been seven cases of smallpox removed from trains during the month. The first six cases were removed to the Chicago smallpox hospital, and the remaining one, which was discovered at East St. Louis on the Indianapolis & St. Louis Railroad, was taken to the St. Louis quarantine hospital. The infected cars were side-tracked and thoroughly cleansed and disinfected, and all exposed individuals were at once vaccinated.

SMALLPOX IN SOUTHERN AFRICA.—This disease, which has been exceedingly virulent at Cape Town for some time back, has made its appearance at St. Paul de Loanda on the south-west coast. During September, the first month of its presence, there were 178 cases reported, of which 95 proved fatal. The government is taking active steps to meet the disease and restrain it. Vaccination has been made compulsory, and the vaccinating surgeons are supported by a body guard from the Portuguese military forces.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending November 25, 1882, indicate that influenza, diphtheria, and inflammation of the bowels have increased, and that puerperal fever, dysentery, and cholera morbus decreased in area of prevalence.

Including reports by regular observers, and others, diphtheria was reported present during the week ending November 25, and since, at 22 places, scarlet fever at 13 places, and measles at 5 places. Smallpox was reported at Grand Rapids, November 25.

OBITUARY RECORD.—At Newark, N.J., of heart disease, on November 28, in the sixty-first year of his age, ALEXANDER N. DOUGHERTY, M.D., late President of the New Jersey State Medical Society.

Dr. Dougherty was born in Newark, on January 1, 1822. He was educated at Oberlin College, and received his medical degree from the College of Physicians and Surgeons of New York, in 1845. In 1861, he was commissioned a Surgeon of Volunteers, and was made Medical Director of the 2d Army Corps, and subsequently of the Right Grand Division (2d and 9th Corps) of the Army of the Potomac. He was wounded in the battle of the Wilderness. At the close of the war he was mustered out of the service with the rank of Brevet-Colonel. In 1866, he was appointed Postmaster at Newark, and served for two years. He was formerly President of the Essex County Medical Society, and in 1880 he was elected President of the State Medical Society. He was Surgeon and Commandant of the New Jersey Home for Disabled Soldiers, at Newark; and Surgeon to St. Michael's Hospital, Newark. The Essex County Medical Society adopted appropriate resolutions on the death of their late President. Dr. Dougherty's funeral was attended by General Hancock and staff, General Campbell and staff of the New Jersey Grand Army of the Republic, the various Grand Army posts of Newark and Orange, and the inmates of the Soldiers' Home at Newark, besides various societies.

——— DIED in New York, on December 2, 1882, in the forty-fifth year of his age, DR. JOHN PHILLIPS PAYSON WHITE, M.D., attending surgeon to Bellevue Hospital. Dr. White was born in Southampton, July 4, 1838. He graduated in the arts at Williams College, and later in medicine at the College of Physicians and Surgeons in New York. When the Rebellion broke out, he accepted a commission as Assistant Surgeon of the 9th New York Volunteer Infantry. He was soon made a surgeon, and in the latter part of the year was appointed medical purveyor of the Army of the Potomac. He accompanied General Burnside on his expedition to the Carolinas, and on returning entered the 10th New York Volunteers. He was temporarily Medical Director of a division of the Army of the Potomac, and subsequently was made Assistant Surgeon-General, with the rank of Lieutenant-Colonel. He was consulting physician of the Women's College, and a member of the New York State Medical Society and Academy of Medicine.

RESOLUTIONS OF THE RAMSEY COUNTY MEDICAL SOCIETY ON THE DEATH OF DR. WHILLDIN.—At a meeting of the Ramsey County Medical Society, the following action was taken with reference to the death of DR. WHILLDIN, of Saint Paul.

Whereas, Our friend and associate, DR. JOHN S. WHILLDIN, has been suddenly removed by death; and

Whereas, Even during his brief residence among us he had greatly commended himself to our esteem by his upright character, his uniform courtesy and kindliness, and his many engaging qualities; therefore, be it

Resolved, That in Dr. Whilldin we recognize the traits which justly entitle him to be remembered as a sincere friend, a thoroughly competent physician, and a Christian gentleman.

Resolved, That in Dr. Whilldin's death we have not only suffered personal loss, but that our Society and profession have been deprived of one who promised to contribute materially to their success and usefulness.

Resolved, That these resolutions be published in the *Pioneer-Press* of this city, and in the MEDICAL NEWS, of Philadelphia.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 27 TO DECEMBER 4, 1882.

CALDWELL, DANIEL G., *Captain and Assistant Surgeon.*—Leave of absence granted in Special Orders, No. 105, Oct. 3, 1882, Department of the Platte, extended three months.—*S. O. 279, A. G. O., December* 1, 1882.

POWELL, J. L., *Assistant Surgeon.*—Relieved from temporary duty as attending surgeon at headquarters Department of Texas, and to proceed to Fort Davis, Texas, and report to the commanding officer for duty.—*S. O. 129, Department of Texas, November* 23, 1882.

GRAY, WILLIAM W., *First Lieutenant and Assistant Surgeon.*—The leave of absence granted on surgeon's certificate of disability, October 31, 1882, Department of the South, is extended five months on surgeon's certificate of disability.—*Par. 3, S. O. 278, A. G. O., November* 29, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE TREATMENT OF SPINAL DISEASES.

A clinical lecture delivered at the Jefferson Medical College, Session of 1882–83.

BY ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF MATERIA MEDICA AND GENERAL THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

GENTLEMEN: No thoughtful student can have failed to observe the greater attention paid to the pathology and diagnosis of spinal diseases than to their therapy. Indeed, the treatment is usually dismissed in a few words, as an unsatisfactory subject. Notwithstanding I have, myself, as a teacher of therapeutics, given rather more than ordinary attention during my lectures here to this department of the subject, I must still admit that my efforts in this direction have not been as full as the importance of the subject demands. I have now to make an effort to supply this omission—to place before you the more recent results attained in the treatment of spinal affections. By thus taking a comprehensive view of the whole field, we may the better comprehend the relation of the several parts and arrive at conclusions more accurately than by the consideration of individual maladies only.

From the therapeutical point of view, these spinal diseases may be comprehended in three groups: Acute inflammatory, chronic inflammatory, and nutritional diseases. It is of no special importance to fix the precise seat of the inflammation, for the principles underlying the therapeutical management are the same. To a just estimate of the curative effect of remedies in these inflammatory affections, a true conception of the spinal circulation is necessary. Look at this diagram. Observe the voluminous and tortuous veins of the spinal canal. To the nutritious arteries of the cord they bear the numerical proportion of four to one. In other words, if the capacity of the arterial supply be put at *one*, the venous capacity must be stated as *four*. It follows that the blood current sent into the spinal canal through the arteries must be slowed there to fill out the veins. This, you will explain, is an arrangement to facilitate the functional work of the spinal cord, under the various conditions interfering with the normal and equable blood-supply. Without stopping to consider the necessity, we are now concerned with the fact, simply. The blood-supply having this peculiar arrangement, do these anatomical conditions affect the question of remedies? I unhesitatingly answer this question in the affirmative.

One of the remedies most relied on to affect the intra-spinal circulation is ergot. I hold that its administration in acute spinal inflammation is improper, because of the peculiarity of its action. It induces an anæmia of the arterial distribution—an ischæmia, properly speaking—but the blood, thus driven from the arterial side, accumulates on the venous side; hence it follows that whilst the arterial supply may be reduced, the veins of the spinal canal are distended unduly. The compression thus exerted on the cord has, as I conceive, a most hurtful influence on its nutrition, and hastens the progress of the changes inaugurated by the inflammation.

If ergot is inadmissible in acute inflammation of the intra-spinal organs, to what remedies shall we then resort? You may not be at all prepared for the statement I have to make, but, speaking from the standpoint of my personal observation, I have to say that aconite, digitalis, veratrum viride, opium, and bromide of potassium are the most useful remedies in the cases of acute spinal inflammation. Each, however, has its special range of utility. All agree in the power to limit the blood supply to the spinal canal, but in what degree, if at all, does each affect the intra-spinal venous circulation? Far more than ergot. If I may again refer to my own experience, I can recommend the use of digitalis first, and, if this disagree with the stomach, aconite. You will find it most useful to begin with the infusion of digitalis, administering from a tea- to a tablespoonful every four hours, until the conditions for which it is used cease, or the stomach fails to retain it. If irritability of the stomach is a bar to its internal use, it may be effectively employed topically, the leaves being steeped in hot water, placed in a porous bag, and applied to the spine or abdomen. This remedy, you will find, will do more to restore the normal balance of the intra-spinal circulation than any other now at our command.

Next to it in point of utility is the tincture of aconite root. This must be given until the characteristic tingling is produced, or the pulse-rate is lowered. Acting both on the skin and kidneys, it favors the excretion of the products of inflammatory waste. Veratrum viride is not as useful as aconite—its action little extending beyond the hydrostatic effects. Opium, especially morphia, hypodermatically, becomes indispensable when pain is a pronounced feature in all cases, and experience has shown its utility in meningeal inflammation. The bromides, especially bromide of potassium, are indicated when reflex, convulsive phenomena are present; such as muscular cramp, twitchings, etc., indicating irritation of the motor tract.

Are there any data by means of which we may fix the time for the administration of the arterial sedatives? As these remedies only affect the vessels primarily, and secondarily the structure of tissue, when shall they be discontinued? In respect to this point, there is always no little indecision; but a correct conclusion may be reached by a careful consideration of those symptoms, indicating the occurrence of exudations—symptoms whether of excitation or of depression of function. So long as the symptoms of excitation—hyperæsthesia and spasm—continue, there can be no doubt that those remedies will be useful which have to do with the blood supply. When exudations occur and pressure is thereby brought to bear on the intra-spinal organs, the symptoms of depression or of arrest of function come on—anæsthesia and paresis.

Arterial depressants can do no possible good; only injury, indeed, when the local status is no longer that of hyperæmia and excited action; when the process of effusion and exudation comes on, we have to deal with depression of function. Remedies having very different powers then come into use.

Merely fluid effusion into the spinal canal is more easily disposed of than a solid exudation. Usually, however, the products of inflammation include both fluid and solid exudations. Absorption of merely fluid exudation may be affected by a judicious combination of purgatives and diaphoretics, especially of Epsom salts and pilocarpine. The disposition of solid exudations is more difficult. Considerable experience with the use of ammonia and its salts, especially of the

acetate and carbonate, has given me very positive confidence in the power of this remedy. The most convenient mode of administering it is to dissolve the carbonate in the officinal *liquor ammonii acetatis*, so that five grains of the former will be given in a tablespoonful of the latter. At or about the time when the symptoms of depression, due to the pouring out of an exudation, come on, the solution of ammonia should be administered. The important point is to so alkalinize the blood, that local thrombus and solid exudations may be reabsorbed. To accomplish this result, it is necessary to keep the blood well alkalinized. Although this may fail, it is surely the most promising expedient in such cases, and experience has proved its utility.

If the physician is so fortunate as to see the case at the very moment of its inception, the best results are to be expected from the administration of a maximum dose of quinine and morphine—20 grains of the former and one-half grain of the latter; but unfortunately, cases of acute spinal inflammation are not often seen at their beginning. The attempts to jugulate an inflammation can therefore be very rarely made with success. The cases of chronic inflammation are relatively more frequent. They succeed to the acute; they may arise *de novo*. Hyperplasia of the neuroglia, granular degeneration of nerve fibres and cells, fatty and granular degeneration of the intima of the vessels, and crowding of the perivascular lymph-spaces with leucocytes, are the most important initial changes, and these lead to various inflammatory and atrophic lesions. The various scleroses belong to the group of chronic inflammatory affections—such as antero-lateral and posterior spinal sclerosis. The alterations extend over many years, but they are, properly speaking, of the chronic inflammatory type. It must be obvious to you that some of the most important therapeutical questions are concerned in the management of these affections. The means employed are partly topical; partly systemic. A daily morning and evening hot douche to the spine, of fifteen minute's duration. I have found it to be exceedingly effective.

In the absence of suitable appliances for the douche, a sponge dipped in hot water and passed over the spine rapidly for fifteen minutes at a time may be accepted as its equivalent. You may regard this as trivial, but I assure you the day of small things has not yet passed. The importance of physical impressions on the peripheral nerves is indeed very great. Strumpf, the well-known neurologist of Düsseldorf, has lately got remarkable curative results in posterior spinal sclerosis by cutaneous faradization, by excitation with the faradic brush of the skin of the back, especially of the spine and of the limbs. This method consists in passing the faradic brush for a half hour at a time thoroughly over the parts in which the lesion is known to exist, and over those parts in which symptoms are felt. You will probably feel inclined to ask, How can cutaneous faradization effect the cure of a disease which has hitherto resisted the most efficient treatment? It may be quite impossible to give an adequate explanation, but it is certain that peripheral irritation, if restrained within proper limits, has a remarkable curative effect on the condition of internal organs so situated as to be in anatomical relation to the site of irritation. Thus, Strumpf has found that cutaneous faradization of one side will cause an increase of the temperature in the corresponding position on the other side. Erb strongly advocates the use of the rubbing wet-pack in chronic myelitis. He does not advise cold or hot water, but merely tepid. The patient, enveloped in a sheet wrung out in tepid water, is gently rubbed with the sheet *in situ*. To the same class of actions belongs massage, but this alone has, in my experience, been disappointing. If the application can be confined to the gentlest titillation of the cutaneous nerves, good may come of it; but in the spinal trouble I am referring to, all violent rubbing and kneading apparently does mischief. Granville's *percutier*, lightly used, has a good effect also. It is a matter within the range of everybody's experience that the most painful inflamed surface will be anæsthetized by the gentlest friction if persistently employed. It is probable, therefore, that the good effects of peripheral applications in spinal affections are largely due to the communication of very gentle impulses originated at the periphery, in the sensory terminals.

Besides these topical applications which act through the sensory nerves, there is a local remedy which acts directly on the cord—galvanism. Since it has been shown that the galvanic current penetrates through the bony envelope of the cord, the only question is as to the mode of applying the electrodes. Strangely enough, opinions are yet divided as to the effect of direct or inverse currents. My own conviction is, that the view of Onimus and Legros is substantially correct. According to them, the descending galvanic current increases the activity of the circulation in the part acted on, by stimulating the vermicular contractions of the organic muscular fibre of the vessels. The result of such increased vermicular motion, must necessarily be a more active circulation, and more rapid interchanges between the blood and the tissues. A descending galvanic current must therefore promote the nutrition of parts, if we admit the correctness of the views enunciated by Onimus and Legros. It is, therefore, in chronic spinal affections that we have a right to expect the best results from galvanic treatment. As the resistance offered by the bones of the spinal column is so great, the electro-motive force of the galvanic battery must be sufficient to overcome it.

To treat such cases efficiently, not only must the number of elements be large, but the resistance within the battery must be nearly that of the part of the body acted upon, to avoid the shock and burning pain. The electrodes should be of large, well-moistened sponges—one placed on the nape of the neck, the other on the sacrum. As the strength of current required for these spinal applications is so great, unless the sponges are large and well moistened, very severe burning will be produced. The number of elements required will be from thirty to sixty, or the strength in *milleampères*, from ten to twenty. There should be a daily *séance* of ten to fifteen minutes' duration, and the treatment should be continued over many months to obtain permanent results. It is the neglect of these measures, inattention to details, and impatience over delays that have led to so much disappointment in the application of galvanism. I am, from personal observation, fully able to confirm the high estimate placed by Erb on this method of treating chronic spinal affections. Neither galvanism nor any other remedy can restore lost parts; hence, when the anatomical elements are destroyed, function must ever after be imperfectly performed.

I must now call your attention to the most useful internal remedies in chronic cases of spinal inflammation. The best results have been obtained from the so-called metallic tonics, notably nitrate of silver, but the danger of staining and of causing gastric ulceration are serious objections to the persistent administration of silver salts. In the scleroses, and in connective tissue hyperplasia of organs in general, I have seen excellent results from the internal use of the chloride of gold and sodium. This may be given in a granule containing one-twentieth of a grain three times a day. The corrosive chloride of mercury has similar effects, but it does not seem to me to be equal in curative power to the gold chloride.

There are so many ways, owing to the almost universal use in domestic life of the noxious metals, for slow metallic poisoning to occur, that the affections thus produced are probably much more numerous than we are now aware of. A typical example of locomotor ataxia came into my hands, in the person of a water gilder. Syphilis is now held to be the chief pathogenetic factor in this disease, but there are two modes in which this relation exists—direct and indirect. Syphiloma occurs when the first cutaneous lesions appear, but especially during the time of the older constitutional symptoms. The first are comparatively mild, the second consist of gummata, etc. These lesions are direct—that is, they belong to the ordinary course of development—of evolution of the disease. The indirect arise because of the cachexia—the lowered vital resistance of the organism, produced by the long-continued operation of the syphilitic disease and of the remedies used to remove it. In the former, or the direct syphilitic lesions, the specific remedies are curative; in the latter or indirect, they rarely do good; in fact, their administration is adding insult to injury, in many instances.

I have long entertained the notion that the utility—the remarkable utility—of iodide of potassium in some cases is due to one of two conditions: to an overlooked syphilitic infection; to metallic poisoning. This is so certainly a fact, that in doubtful cases I advise the use of full doses of iodide of potassium as a preliminary to further treatment. In all distinctly specific cases there can be no possible doubt in regard to the efficacy of anti-syphilitic treatment. Now let me tell you a fact not generally known, or, if known, not sufficiently appreciated: Mercury, in syphiloma of the nervous system, tertiary in type, is, in some instances, quickly curative when the iodides fail utterly. *When there is reason to suspect mineral poisoning, and in all doubtful cases, the iodides should be administered in full doses, either tentatively or as the major treatment.*

The third group, from the therapeutical point of view, consists of those spinal disorders not due to a recognizable inflammatory process, but to some change in the function of nutrition. In this position may be placed the changes that are senile, whether of time or prematurely. The most important therapeutical point in these cases is to supply the material in which the tissues are deficient. A combination of the lime salts—the phosphate especially—with a fat, cod-liver oil, is most useful in these cases, but good results can be reached only by persistent use of the means of treatment. In these cases of senile degeneration, much good is accomplished by the use of the salts of ammonia to prevent the formation of thromboses, or to effect their solution if formed. Strychnia and quinine, to stimulate the organic functions, render an important service also.

The subcutaneous use of strychnia is often remarkably effective in all of the chronic spinal affections characterized by loss of muscular power. It is, of course, inadmissable in those stages of these maladies having an active state of the local circulation—in all acute cases, in chronic cases with acute exacerbations. The quantity to use in this way ranges from $\frac{1}{60}$ to $\frac{1}{30}$ grain daily, once, or on alternate days. The hypodermatic injection of strychnia may, indeed, serve as a means of distinguishing the character of the spinal trouble. It increases the paralytic symptoms when an inflammatory condition is present, and improves the functional and chronic diseases.

Galvanism, applied as already pointed out, to stimulate the spinal circulation, and faradism at the periphery, contribute to the nutrition of the cord by promoting the activity of the circulation in general. By a proper combination of these expedients, we can often effect very decided improvement.

As you will observe, I have not alluded to the treatment of the large group of so-called functional disorders of the spinal cord. The consideration of this is a sufficiently fruitful topic of itself for a lecture—for many lectures, indeed—and hence I must postpone it to a more convenient season.

ORIGINAL ARTICLES.

PNEUMO-URIA.

BY E. L. KEYES, M.D.,
PROFESSOR OF CUTANEOUS AND GENITO-URINARY DISEASES IN BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO BELLEVUE HOSPITAL, NEW YORK.

SURGEONS are for the most part in accord in believing that when gas is found within the human bladder its presence there is to be accounted for only by assuming that it has been introduced from without, through the urethra, or through a vesico-intestinal fistula, or that it is due to decomposition of the urine, or of blood-clot in the urine.

That a gas resembling air, colorless, sweet and pure, not ammoniacal, not sulphuretted hydrogen, and not introduced from without, that such a gas may form within the bladder is not generally credited by the best-informed members of the medical profession.

Having two cases bearing directly upon this question I think it proper to place them on record, the more so since I find that the subject has been already alluded to by several writers, notably Bouchut, and the malady by him considered a neurosis. The name pneumo-uria was given it by Raciborski.

The record of the following cases may serve to call attention to the subject and bring to light other instances in point.

CASE I.—In February, 1868, a gentleman of 67 applied to Dr. Van Buren for relief from frequency of urination with some urgency in the desire to accomplish the act, with night calls, etc., symptoms from which he had suffered for ten years, and which were plainly due to failure in expulsive energy on the part of the bladder and to a prostate one-third larger than normal. His urine was acid, 1020, containing a small amount of pus. He could not entirely empty his bladder. There was no gas in the bladder at this date.

Under the use of a catheter improvement in urination was noted, but gradually with a steady increase in the size of the prostate it became impossible for the patient to retain his water, when the call to urinate came suddenly upon him, and he was forced to resort to the use of a urinal in travelling, and upon going out in the evening. Later it became impossible to pass any instrument into the bladder, and finally, in the summer of 1873, the patient died from kidney disease in the classical mode of death commonly attendant upon prolonged obstructive prostatic disease.

I never attended him directly until during his last days. Dr. Van Buren remembers that the patient passed gas occasionally from his penis, but I made

no especial note of the fact and cannot remember the dates, although I do remember examining the urine for Dr. Van Buren, for foreign matter and finding none.

After death the body was placed immediately upon ice, and in about twenty-four hours I made an autopsy, mainly to determine why instruments would not enter the bladder.

On opening the abdomen the bladder was seen fully distended, and evidently about half-full of gas. There was no evidence of decomposition about the intestines. The outside of the bladder was not inflamed or adherent to any intestine. I inferred at once that the gas had entered the bladder from a fistula communicating with the bowel, and therefore cut into its dome, allowing all the gas to escape, that I might examine the perforation *in situ*. The bas-fond of the bladder contained urine not putrid—and, as I remember it, not specially ammoniacal—but I searched in vain for a perforation. No fecal matter was in the bladder. I searched among the small intestines and along the top of the bladder, but found no perforation. I removed the bladder, but obtained no clue to the possible source of the gas.

I therefore concluded that the gas was due to some form of decomposition of the urine and made no further investigation. The prostate was quite large and its canal distorted, thus explaining why no instrument had found its way into the bladder.

This case is suggestive only, not demonstrative. The gas was never examined. I had never heard of the existence of gas in the bladder at that date, except as a result of fistula into the intestine. I did not preserve the bladder. I took no written notes at the time of making the autopsy, and my memory as to the exact condition of the urine may be defective. I therefore present the case for what it may be worth. It puzzled me at the time. Whether it was a case of true pneumo-uria or not, I cannot say. It seems to me possible that it was.

Case II.—X., aged 68, was referred to me by Dr. Schnetter, in September, 1868, his complaint being frequent urination by day and by night, and the passage of wind by the urethra. His frequency of urination had existed something more than a year. He had begun to pass air by the urethra only a few days before visiting me. His urine was alkaline, 1030, containing a little pus; but no starch granules, meat fibres, or other foreign matter. The fluid was murky and possessed of a faintly sweetish ammoniacal odor. A No. 18 (French scale) Mercier catheter entered the bladder without encountering any obstacle, and through it escaped two ounces of reasonably clear urine, followed by a small amount of gas, devoid of any odor. The prostate was slightly enlarged. The patient complained of much pain in the perineum and rectum.

Both testicles became swollen on different occasions later on, and he had considerable discomfort from suppurative eczematous outbreaks about the thighs and scrotum. He was treated symptomatically for these complications, and by sounds and attempts at vesical irrigation together with alkaline diluents, anodynes, and tonics. But he failed steadily in general health and became quite yellow and cachectic. The most minute microscopic examinations of the urinary sediment, carefully repeated at short intervals, were uniformly negative in their results, so far as finding any foreign body that might have come from the intestine was concerned.

In December I asked Dr. Weir to see the patient with me, and we examined him very carefully under ether, with the coöperation of Dr. Schnetter, and of Dr. Ferdinand, of Harlem. Rectal examination showed a prostate but little enlarged. Between the rectum and the bladder, particularly on the left side, there existed a distinct inflammatory thickening of the vesico-rectal septum; it was smooth and regular, not at all nodular, and not suggestive of cancer. On the rectal side as far as the finger could reach, or the eye by the aid of a speculum, there was no ulceration, erosion, or fistula. The inflammatory thickening extended higher than the finger could reach.

A sound in the bladder felt through the vesico-rectal walls showed a moderate amount of thickening not nodular in character. Through a soft catheter the bladder was injected to its fullest capacity under pressure, but no fluid could be seen to trickle into the rectum with the speculum in position. No growth could be felt within the bladder by the searcher. No stone was present.

No chill followed this examination, but the amount of gas passed by the urethra became greatly increased; the urine ammoniacal and putrid. Dr. Ferdinand examined the gas and found it to contain sulphuretted hydrogen. I examined the gas and found it to contain sulphuretted hydrogen; the urine also contained considerable sulphuretted hydrogen in solution. No vegetable cells or meat fibres, or other débris of food, could be found in the urine. Pus, altered epithelial cells, and blood, constituted the deposit, with a few crystals of uric acid, and of triple phosphate.

Under cod-liver oil and local and general measures, the patient's strength and health gradually improved, so that two months later, in February, 1882, the urine was clear and sparkling, 1020, acid, and contained only a few pus cells; but the gas continued. I now drew off the urine and caught the gas for examination, finding it free from sulphuretted hydrogen. The urine was now not ammoniacal, and contained no sulphuretted hydrogen.

This condition of affairs continued through the spring with a gradual gain in ordinary health and strength. In the month of March the bowels became deranged, and the patient passed great quantities of very offensive gas by the rectum. During this period the quantity of gas passed by the urethra greatly diminished, and what did escape was perfectly sweet. In April, the gas from the rectum nearly ceased, while that from the bladder greatly increased in quantity.

In April, the urine being quite clear, I passed a catheter in my office, and drew off under a water-bath into a test-tube 30 cc. of gas, more than an equal quantity escaping after the tube was full. I corked the tube tightly while it was still under water,

and sent it immediately to Prof. Welch, of Bellevue Hospital Medical College, for examination. He pronounced the gas to be simple air, and ventured in explanation that whatever other gas was within the tube had diffused itself through the cork, yet he had the tube within the hour after it had been filled and tightly corked, and his examination corresponded with mine, which was made on the spot.

In May the patient had reached his full normal weight, 149 pounds; the urine continued clear and acid, with a very trifling amount of pus; the gas persisted, but was perfectly sweet.

In July I sent the patient to Europe with letters to Sir Henry Thompson and to Felix Guion. Sir Henry examined him quite thoroughly, and reported to me a negative result. The patient had no gas in his bladder at the time of the examination. No tumor was found by rectal examination, or by the searcher; yet, as there had been occasional slight hæmaturia, and as there were some distorted epithelial cells with large nuclei in the urine, Sir Henry leaned to a diagnosis of cancer, and advised exploration by the finger through the perineum on the patient's return to New York. As to gas in the bladder, Sir Henry observed in his letter: "I have never seen any evidence to my mind warranting me to believe in the production of gas in the bladder, apart from its introduction by the intestine or from without. I by no means deny the possibility, and would be greatly interested in seeing such a case," etc. The patient was made so sore by the thorough examination of Thompson, that he feared to visit Guion; but went in Paris to see Mallez, who did not examine him physically, and gave no opinion except that gas in the bladder was not very uncommon. In France the patient improved daily during twenty-four days, eating and drinking whatever he liked. He passed no gas. No blood escaped his urethra after leaving London, and he returned to New York in the middle of October, passing acid, clear urine, with a light sediment of pus, still passing gas and urinating altogether too frequently; but having gained a number of pounds on his trip, feeling strong and reasonably well, and looking vastly better than at any time for the past eighteen months.

The gas in this case has never contained sulphuretted hydrogen when the urine was clear and acid. Dr. Schnetter ventured the opinion that a communication existed between the bladder and the small intestine, the gases of which intestine are usually air and carbonic acid—but the urine did not contain any excess of carbonates. The gas has not been examined for carbonic acid. It is difficult to obtain it, as the patient objects to the use of a catheter. Moreover, the cellulitis only seemed to involve the vesico-rectal septum. It is to be noted that when the intestines were full of gas, the bladder did not contain as much gas as usual.

There was never any evidence of an escape of urine into the intestinal passages, and certainly no débris of food could ever be detected in the urine. An opening, if one existed, must have been either the track of an abscess (due to the cellulitis) or a cancerous erosion. It could not have been the latter, since the patient's health has improved immensely for six months. If it was the track of an abscess, it must have been very minute, since no urine ever passed through it into the bowel, and it should have closed when the cellulitis got well; Thompson discovered no evidences of cellulitis by the rectal touch.

That there is no intestinal fistula in this case I cannot assert, since the crucial test of an autopsy is lacking; yet the character of the gas and of the urine both tend to substantiate a belief that this may be one of those peculiar cases where a gas resembling air forms in the bladder from causes as yet not understood.

I have found in the literature of the subject two such cases sufficiently accurate in their description to make them acceptable, but unfortunately I have found no case verified by an autopsy, so that the sceptical are still justified in doubting. My own recorded autopsy fails to be conclusive only on the ground that no chemical examination was made of the urine to eliminate the possibility of the decomposition of that fluid as a factor in the gas formation. My memory of the condition of the urine, however, is quite clear. I am absolutely certain that the urine was not putrid.

But for the rarity of the occurrence of the phenomenon, it is not harder to believe that the walls of the bladder can secrete air than to believe the same of the walls of the stomach or intestine. It is not so extraordinary or inexplicable as the colpohyperplasia cystica[1] of Winkel (vaginitis emphysematosa), or any more strange than the formation of gas in the uterus, as vouched for by Bianchi, Astruc, Cullen, and referred to by A. Brierre de Boisemont in his interesting thesis, "*Recherches sur les Pneumatoses, ou sécrétions gazeuses observées dans divers tissus de l'Economie animale.*"[2]

This thesis indeed makes the clearest mention of air in the bladder which I have been able to find, referring as it does, without detail, to a case reported by Wedel in the *Miscellanea curiosa*, p. 85, and stating that Ribes, when prosector to the Medical School at Paris, showed his students an infant whose only malady was the passage of gas by the penis ("qui n'avait pour toute maladie que cette émission de gaz"). He states further that the urine was in no way decomposed, but had all the characters of the urine of a healthy individual.

The most closely observed case of this malady which I have found is one reported by Raciborski, and given at length under the name pneumo-uria in Bouchut's treatise *Du Nervosisme.*[3] I condense it as follows: M. O., 40, a nervous hypochondriacal individual, became alarmed at seeing bubbles of air escape from the meatus toward the end of the act of urination. Raciborski visited him, having the urinary specialist Mercier and the chemist Mialhe in consultation. The latter drew off through a catheter the odorless gas which the bladder contained, directing it under water into a receiver. He examined the gas and the urine, finding the latter normal in composition and the former to be

[1] Archiv. fur Gynäkologie, 1877, II., 406.
[2] Thèse de Paris, No. 201, 1825, p. 15.
[3] Second ed., Paris, 1877, p. 245

nitrogen. From this he concluded that the gas was air, the oxygen having been absorbed by the urine. Except nervous symptoms, this patient had had no evidence of any malady of the bladder or of the neighboring organs.

On another occasion, to exclude all foreign sources of air, Mercier passed the catheter upon the patient while he was submerged in a full bath—this in the presence of Drs. Mialhe and Raciborski. Air was obtained as before.

Once, after a voyage of four days to Bordeaux, no gas was found in the bladder on passing the catheter —an analogy with the respite of twenty-four days which my patient experienced after his voyage from New York to Paris.

Raciborski's patient often had difficulty in voiding the urine, particularly in the morning, and sometimes had to make repeated efforts before he could empty the bladder. He had also pains in the renal regions, about the bladder, loins, groins, and thighs. A postscriptum to the case states that during two weeks no air had been found by the catheter, introduced on two occasions, and here the history ceases abruptly.

These few particulars are all the details I can offer concerning this strange malady, pneumo-uria. Its existence is not yet clearly proved, but Mallez seems to accept it, since he assured my patient, who saw him in Paris, that it was far from uncommon for gas to form in the bladder, and that he, the patient, should not be too much concerned about it. Closer observation of cases of this sort is desirable, and an example of it, carefully studied through life, and verified by a reliable autopsy, would be of the utmost value in establishing the existence of the malady upon a sound basis.

CLINICAL REMARKS ON SEVERAL CASES OF PANCREATIC DISEASE.

BY WILLIAM PEPPER, M.D., LL.D.,
PROVOST AND PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

IT is unfortunate to have much to say, and yet to have no intelligible language in which to express it. This is somewhat the lot of the pancreas. Composed as this organ is of lobulated glandular tissue, with abundant interstitial connective tissue, and with a system of ducts to carry off the secretions, and well supplied with nerves and bloodvessels, it could not be otherwise than that it should be liable to a variety of diseases.

Morbid anatomy teaches us, accordingly, that the glandular tissue may be the seat of degenerations; the interstitial tissue the seat of inflammation or of neoplasms; and the secretory ducts, the seat of catarrhal inflammation, of calculous formations, or of cystic distention. We are familiar anatomically with fatty degeneration of the pancreas; with atrophic and hypertrophic cirrhosis; with cancer and other morbid growths; with occlusion of the main duct and distention of its radicles; with impaction of the duct; with altered sebaceous secretion; and with pancreatic calculi. But it must be admitted that, clinically, many of these conditions are scarcely present in our minds as actual realities, to be taken into account and searched after in our study of cases of abdominal disease.

The reason of this is not far to seek. The anatomical position and relations of the pancreas render it almost inaccessible to minute examination; the colorless character of its secretion prevents any discoloration of the skin when the duct is obstructed; and the juxtaposition of the stomach, the liver, and the kidneys, the diseases of which are so common and so prominently present in our thoughts, is apt to lead us to refer any symptom of pancreatic disease to some of these other organs.

It can not be doubted, unfortunately, that the inevitable result of this is the frequent failure to recognize important affections of the pancreas, and the reference of the symptoms present to some rather unusual form of gastric or hepatic disease. It may be said, indeed, that but little practical evil results from this, since in the first place many of the affections of the pancreas are incurable, and in the second, the condition of stomach or liver which is erroneously substituted in the diagnosis, will probably be of a character analagous to that actually present in the pancreas, and thus the line of treatment adopted will not be seriously inappropriate. This is a poor excuse, however, and all will acknowledge that if accurate diagnosis of pancreatic diseases were possible, it would be an immense satisfaction to all concerned, would lead to much more reliable prognosis, and would furnish therapeutic indications which might eventually lead to substantial advances in the treatment of these affections. I do not aspire, in the present brief article, to throw any new light on this obscure subject, but merely to record, with a few practical comments, several cases of pancreatic disease that have come under my observation within the past year.

CASE I. *Hypertrophic cirrhosis of liver, with perihepatitis; hypertrophic cirrhosis of pancreas, with chronic catarrh of its duct; chronic catarrhal nephritis; jaundice; ascites; albuminuria; death.*—Emma A., aged 39, of intemperate and immoral habits, and addicted to the use of cigarettes, was admitted to the University Hospital October 12, 1882, and died October 19, 1882. She had had slight, irregular dyspeptic attacks, with habitual constipation, for a year; previous to which time she was strong and healthy. During this year a steadily progressive abdominal enlargement was observed; there was also pain in the abdomen, especially in region of liver, at first dull and occasional, latterly more severe and constant; for the past eight months there had been anorexia and frequent vomiting after taking food (no blood was ever vomited); menstruation ceased eight months ago, and for the past five months there had been occasional epistaxis; jaundice with bile-stained urine began two months ago, and has grown intense; loss of flesh and debility have been steadily progressive. On admission, her weakness was extreme and there were enormous ascites, deep jaundice, albuminuria with granular tube-casts, great enlargement of the liver, and loose, offensive stools. Paracentesis gave temporary relief,

but ascites rapidly returned, and she sank and died seven days after admission.

At the *post-mortem* examination there was hypertrophic cirrhosis of the liver, with marked perihepatitis. There was chronic catarrhal inflammation of the gall-ducts, with marked contraction of the cystic duct and distention of the gall-bladder with thin, pale, yellow mucus.

The pancreas presented a marked state of hypertrophic cirrhosis, with peri-pancreatitis. The pancreatic duct was much narrowed and obstructed by catarrhal products. On section, multitudes of minute collections of cheesy matter were seen to distend the acini of the gland. These statements are abstracted from the admirable report of the necropsy, furnished me by Dr. Formad, who also described the microscopic appearances as showing advanced atrophy of the gland elements, with extensive overgrowth of connective tissue (hypertrophic cirrhosis). In addition, all of the parts which had presented themselves to the naked eye, as little cysts filled with cheesy masses, revealed tubercular granulations with giant cells, obliteration of bloodvessels and well pronounced cheesy changes, these indicating a local tubercular change consequent upon the chronic catarrhal inflammation. The kidneys were in the second stage of catarrhal nephritis.

In this interesting case, which shows so well the pathological affinities of the pancreas and liver, it will be observed that advanced lesions of the pancreas, illustrating cirrhotic inflammation combined with the much more rare form of chronic catarrhal inflammation, described by Klebs under the questionable name of pancreatic acne, were present, and yet would scarcely have been suspected to exist, so completely were any symptoms they may have produced overshadowed by the symptoms of the readily recognized disease of the liver and kidneys. The pain was distinctly referable to the perihepatitis; the jaundice was readily explained by the catarrhal hepatitis, that was evidently associated, as is often the case, with the hypertrophic cirrhosis; and the vomiting, which was much more frequent than in ordinary uncomplicated cirrhosis, was not unreasonably connected with chronic gastric catarrh and the catarrhal nephritis. The brief period the case was under observation prevented an accurate determination of the absence or presence of fatty stools; and there was not even so great a degree of emaciation as might be expected, in so severe and complicated a case. It can not, however, be doubted that the course of this case was modified considerably by such grave lesions of an organ so important as the pancreas.

In the following case ample opportunity was given for study of the symptoms, and for the formation of an accurate differential diagnosis, and yet special peculiarities in the symptoms rendered this a very difficult matter.

CASE II. *Cancer of head of pancreas, with central suppuration; occlusion of gall-duct; perforation of duodenum, with temporary relief; return of occlusion; death.*—Mr. W. C. L., æt. 60, had suffered from a severe concussion of the spine many years previously, which had left a certain degree of neurasthenia, with exaggerated sensitiveness of circulation and digestion. For a number of years it was his habit to have two stools daily, not at all loose, but rather too easy. This was mentioned to me in 1879, and with a view to see if it aided in any way in maintaining the neurasthenia, a course of small doses (gr. ⅛ of nitrate of silver) was given, which promptly checked it and reduced the stools to one daily, which was followed by some improvement in general strength. Occasional slight pain in the stomach was complained of in the latter part of 1879. His health was apparently very good, however, subsequent to this, until, after exposing himself at night on the sea in September, 1880, he had some return of pain and looseness. This yielded readily to simple remedies, and although he continued to have occasional pain in the upper part of the abdomen during the fall and early winter, he attended regularly to his business, and did not have medical advice until January 20, 1881, when jaundice appeared with more marked abdominal pain and looseness of the bowels. The jaundice rapidly grew intense, and was accompanied with debility and loss of flesh.

By March 1st, he was very ill with complete occlusion of the common bile-duct; recurring free epistaxis; slight irregular fever, with average evening temperature of 100½°, with occasional sweats, and with a pulse rate of over 100. There was anorexia, and although the diet was restricted the bowels were opened three or four times daily with white, offensive formed passages. The feces passed very readily, and looked slippery, as though containing undigested fat, but no free oil was seen. He was strictly confined to bed; his food was rigidly restricted; counter-irritation was kept up over the liver, and he took internally a pill of nitrate of silver and opium. He then began to improve slowly but steadily; the fever and sweats subsided, the jaundice grew lighter, appetite improved, the stools were reduced to two daily and began to contain bile; the urine, which had been heavily charged with bile-pigment, grew somewhat lighter, and his spirits and strength improved. There was considerable tenderness in the region of the gall-bladder and duct, and this, combined with the thickness of the abdominal walls, rendered difficult any accurate palpation. It was impossible at any time to isolate any distinct mass or tumor, but there was a slight degree of enlargement of the liver with an indistinct sense of increased resistance on palpation about the position of the gall-duct and head of pancreas. While thus apparently improving however, there was no gain in flesh, even if he did not continue to lose weight. By April 1st, the jaundice and evidences of constitutional irritation were much relieved, and about that date an unaccountable bilious diarrhœa occurred for two or three days, when rapidly all traces of bile disappeared from the urine. The looseness soon ceased, and in a few days there was a rapid return of deep jaundice with highly stained and for the first time slightly albuminous urine; epistaxis recurred; the mind grew dull and wandering, to be soon followed by a coma-

tose state, and death occurred on April 25, 1881, with all the symptoms of profound toxæmia.

Post-mortem examination showed that the head of the pancreas was the seat of cancerous degeneration, forming a rounded hard mass about 2½ inches in diameter, which was closely adherent to the duodenum and the common bile-duct. The centre of the cancerous mass was the seat of suppurative softening, forming a cavity of more than one inch in diameter. At the time of making the autopsy this cavity was distended with a puriform liquid, and in this condition it pressed so strongly upon the common bile-duct as to completely occlude it. But at the point where the growth was most closely attached to the duodenum, there had been an lucerative perforation, which at this time was closed by a valve-like fold of mucous membrane. As soon as this was raised and the pus allowed to discharge itself, the walls of the growth collapsed partially and the bile-duct became patulous. It was thus evident that the progressive obstruction of the duct had been occasioned by the increasing growth of the neoplasm in the head of the pancreas, which pressed more and more upon the duct; that the period of slow, progressive improvement must have corresponded with a gradual evacuation of the soften ng centre of the mass through the ulcerated opening in the duodenal wall; that the slight diarrhœa with rapid abatement of jaundice and clearing of the urine corresponded with a more complete discharge of this character, allowing the growth to collapse partly, and thus render patulous the common bile-duct and enable the pent-up bile to rush into the bowel; and that, finally, after the evacuation, the perforation of the duodenal wall closed again, the cavity began to refill with puriform liquid, the bile-duct again became occluded, and by this time the vital powers and the crasis of the blood were so impaired that the patient speedily sank into a typhoid toxæmic state.

While, however, it is easy, after the post-mortem examination, to explain the various symptoms and their relations, it was far otherwise during life. The history of slight abdominal pain, with looseness of the bowels, seemed to point to catarrhal irritation of the mucous membrane, and when in January jaundice appeared and rapidly grew intense, it would not have been unnatural to conclude that the catarrhal inflammation had extended to the gall-duct, and caused such swelling as to occlude it. The irregular fever was consistent with such a supposition, although we are familiar with the fact that a febrile movement of hectic type, the so-called *hepatic fever*, may be associated with occlusion of the gall-duct from any cause, being probably dependent on putrefactive changes in the retained bile, and consequent septic irritation, as well as on aggravated surface irritation of the mucous membrane lining the distended ducts. While, however, it is true that in this way cancer of the head of the pancreas, pressing upon and occluding the common bile-duct, may indirectly give rise to fever, it was to be noted that in the present case the febrile movement existed before the occlusion of the duct became complete. The existence of suppurative softening in a cancerous mass is also apt to be attended with some irregular fever of hectic type, and I have on various occasions seen great embarrassment in differential diagnosis thus created by the coexistence of pyrexia with conditions which otherwise indicated cancerous disease, a morbid process well known to be ordinarily apyretic.

Occasionally, moreover, the existence of a cancerous growth in the abdomen, just as in the thorax, will be accompanied with subacute local inflammation of the peritoneum or pleura, and thus a moderate degree of fever may attend. Despite the various ways in which the pyrexia present in this case might have been explained upon the supposition that cancerous disease existed, it seemed more plausible to attribute the fever and the jaundice to catarrhal inflammation of the intestinal and hepatic mucous membrane; and this view was of course confirmed by the favorable course of the symptoms during the month of March and the early part of April. It is true that, despite this seeming improvement, there was no apparent gain in weight; but it is difficult to judge of small changes in weight while a patient is in bed; it was clear that no great emaciation occurred until the reappearance of intense jaundice; and, finally, it is usual to find considerable loss of flesh consequent on duodeno-hepatic catarrh. The character and locality of the pain afforded no help in diagnosis. It was not severe or constant, and was referred somewhat vaguely to the upper part of the abdomen. It can not be said that pancreatic disease is attended with any characteristic pain, but still our attention would be more drawn to that organ if pain were complained of as deep-seated, at the lower part of the epigastrium, and at a corresponding part of the back.

The detection of a tumor, central or slightly to the right of the median line, deep-seated, and less movable than a pyloric cancer, is possible in some cases of pancreatic disease, and is of high diagnostic value. But it is by no means in all cases that the tumor can thus be detected, even by the most careful palpation. A coincident enlargement of the liver, as in the present case; dilatation of the stomach; thick, fatty abdominal walls, such as existed here also to a very late period, may render its detection impossible. Even when a pancreatic tumor can be felt, it can rarely be accurately mapped out and localized; and if, as not rarely happens, there is frequent vomiting present in consequence of irritation of the stomach, or of its implication in the morbid process, the mass detected is apt to be regarded as of gastric origin.

The condition of the intestinal digestion and the fecal discharges should be studied with minute care in all cases of chronic abdominal disease, and light will occasionally be thrown from this source on the diagnosis of pancreatic disease. It is well known that fatty stools are present in some cases of obstruction of the pancreatic duct or of extensive degeneration of the glandular tissue. It is true that they are sometimes absent, or, at least, that there is no appearance of free fat in the stools; and, on the other hand, it is also true that in severe hepatic disease fatty stools may occur. Still their

presence in any case, especially if deep jaundice be not present at the same time, is certainly a valuable diagnostic symptom. The character of the stools in the case here recorded is instructive, as showing that a mere naked-eye examination is entirely insufficient; for while at no time was any free fatty matter observable, I am confident, from their slippery appearance, that microscopical examination (unfortunately neglected) would have revealed a great excess of unaltered and unabsorbed oil.

Space will not allow me to now report and comment on a case of pancreatic calculus, but it will be presented in a subsequent article. The practical points the cases here published serve to illustrate are, that cirrhosis of the pancreas, which is not a very rare disease, is usually associated with cirrhosis of the liver, and, possibly, also of the kidneys; that its symptoms are apt to be masked by those pertaining to the latter organs; that unusually marked intestinal dyspepsia, with possibly frequent vomiting, an unusually rapid rate of emaciation, and the occurrence of fatty stools, would be the features which would influence us in deciding that in a case of hepatic cirrhosis the pancreas was also involved. And, again, that in malignant disease of the pancreas the symptoms most likely to occur are, in addition to progressive debility and anæmia, pain, vomiting, tumor, jaundice, intestinal indigestion, with tendency to loose and fatty stools; but that in any given case we rarely find all of these symptoms present, and that even when they are, as in the case of Mr. L. here recorded, they require to be analyzed and studied with unusual care, or otherwise there is much risk of confounding the case with one of disease of the liver (cancer, chronic catarrhal inflammation, etc.), or of the liver and stomach combined. Finally, the peculiar train of symptoms induced in the case of Mr. L. by the alternate distention and collapse of the pancreatic tumor, although possibly unique, should be borne in mind in case of a similar group of phenomena occurring in the future.

(*To be continued.*)

HOSPITAL NOTES.

NEW YORK EYE AND EAR INFIRMARY.

(Service of Richard H. Derby, M.D.)

CASE OF HODGKIN'S DISEASE, WITH TUMORS OF BOTH LACHRYMAL GLANDS.

Patient S. B., aged 51, of Nova Scotia; thirty-three years ago had left leg amputated below the knee for disease. Has worn artificial limb and enjoyed general good health. Two years ago first noticed swelling in left groin, a few months later same in right; eighteen months ago had slight ptosis; then complained of drowsiness; within twelve months noticed signs of present deformity about eyes; these ocular changes have not been accompanied with pain—once he had diplopia when he thought on the street a man was driving two horses when in fact there was but one. There has been slight gradual failure of sight up to the present time.

The woodcut shows as well as any single view can the striking features of this case.

Each eye is pushed slightly downward and inward, but there is no exophthalmos, and its movement upward and outward is only moderately limited. On the temporal side of each upper orbital margin, the eyelid is pushed forward by a growth, which feels to the touch tough and resistant, and appears to have its origin within the orbit between eyeball and upper orbital wall. The anterior portion of this is hard, rounded, nowhere sensitive to the touch, and both from position and shape is clearly the lachrymal gland. The tumor of the right side is somewhat larger than that of the other, and the entire tarso-orbital fascia seems to be pulled down by the lachrymal glands.

Patient can voluntarily, but slightly, raise the upper lid from the position depicted in the woodcut; when the lid is raised for him but slightly, the lower portion of the lachrymal gland, firm, tense, and well marked, can be seen on its inner surface.

In the refracting media of the eyes no change can be seen, and the same is true of the retina and optic nerve and the intra-ocular circulation, but the vision is reduced to $\frac{20}{LXX}$ in the right eye and $\frac{20}{L}$ in the left.

This amblyopia is doubtless due to the pressure exerted upon the eye and its appendages by the dislocated and hypertrophied lachrymal glands.

Patient's color is bad—pale, ashy. On each side of the neck are large cervical glands; in both axillæ and in both groins are glandular enlargements; those of groin of the size of hens' eggs at least, and firm and resistant. So on each elbow above the olecranon are glandular hypertrophies, and the post-aural glands are very much enlarged.

MEDICAL PROGRESS.

Modification of Esmarch's Bloodless Method. —Dr. J. Szydlowski proposes the substitution of a simple elastic rubber tube for the band and tube in Esmarch's method. The tube is to be tied in the form

of a ring of a size suitable to the limb on which it is to be applied, passed over the hand or foot, and then gradually rolled up the limb, so compressing the vessels and preventing access of blood to the part, and driving out the blood already present; it is then to be allowed to remain and act as a tourniquet.—*Med. Chirurg. Centralblatt*, November 3, 1882.

THE PHYSICAL SIGNS OF PLEURITIC EFFUSION.—DR. R. DOUGLAS POWELL concludes a lecture on the physical conditions produced by pleuritic effusion as follows:

1. That until the pleura (previously under healthy conditions) is about two-thirds full of fluid, no positive pressure is exercised upon lungs or heart.

2. Up to this point, therefore, there is no tendency for the fluid to escape on puncturing the chest unless air be allowed to replace it. Its removal, otherwise, can only be effected by aspiratory or siphon power.

3. It is only in effusions beyond this point, therefore, that the diaphragm becomes depressed.

4. On the other hand, the heart is necessarily displaced from the very commencement of the effusion, and in proportion to its extent; cardiac displacement being thus a valuable index of effusion, but no measure of intra-thoracic pressure.—*Medical Times and Gazette*, November 18, 1882.

HEMORRHAGE INTO THE CAVITY OF THE ARACHNOID.—In a clinical lecture on this subject, MR. HENRY MORRIS, surgeon to the Middlesex Hospital, points out, as illustrated in a case:

1. That spontaneous effusions into the cavity of the arachnoid—*i. e.*, effusions of blood from disease or excitement—are very often not distinguishable from traumatic effusions. 2. That *post-mortem* examination does not always explain the cause or the source of the effusion, and that the state of the blood-clot is only a very rough test as to the age of the effusion. 3. Extravasation of blood between the dura mater and bone, as also extravasations beneath the visceral arachnoid, accompanied by brain bruising, are almost certainly traumatic, whether fracture coexists or not. Extravasations into the substance of the brain and into the ventricles are almost certainly spontaneous when no fracture and no brain bruising coexist, and are probably so even when fracture without bruising of the cerebral surface is found. 4. Spontaneous effusions may occur without there being any naked-eye evidence of disease of the cerebral or meningeal vessels. 5. Spontaneous effusions into the arachnoid cavity from disease or excitement have occurred as early as the twelfth year of life, and at all ages subsequent to puberty. Inter-arachnoid hemorrhage occurs at any age from violence. 6. In slight injuries to the head, such as small scalp wounds without fracture of the skull, or bruising of the surface of the brain, the surgeon should be extremely cautious in attributing inter-arachnoid extravasation to a blow, and more especially when, as in the case alluded to, the injured person is of intemperate habits.—*Lancet*, Nov. 11, 1882.

MENSTRUATION AND PSEUDO-MENSTRUATION IN DIFFERENT FORMS OF TYPHOID.—DR. E. BARRET, of St. Petersburgh, has studied, in a long series of cases, the influence of various forms of typhoid on the phenomena of menstruation, and formulates his conclusions as follows:

1. The influence of typhoid fever on menstruation will depend upon the time elapsing between the onset of the disease and the menstrual period.

2. When the menstrual period falls within the first five days of the disease, the appearance of the menstrual flow may be confidently expected: it occurred in 100 per cent. of his cases. If it is expected between the sixth and fourteenth days of the disease, it will occur in about 65 per cent. When expected after the fourteenth day, menstruation never appears.

3. The menstrual flow is suppressed more frequently in abdominal typhus than in other forms of the typhoid condition.

4. When present, the character of the menstrual flow is rarely altered in abdominal typhus: in spotted typhus (flecktyphus) it is usually diminished in quantity, and in relapsing typhus it is increased in amount.

5. The second and third menstrual periods rarely occur in any form of typhus.

6. Pseudo-menstruation, or a non-menstrual genital hemorrhage, rarely occurs; in spotted typhus it is a little more common, though it never appears before the age of puberty, or after the menopause.—*Deutsches Arch. f. klin. Med.*, November 8, 1882.

CROUP IN HOLLAND.—In the *Nederlandsch Tijdschrift voor Geneeskunde* for the present year, Dr. J. Korteweg contributes a long and laborious article on Croup in Holland. After a slight reference to the works of Bretonneau, Guersant, and Trousseau, he quotes the experience of various Dutch physicians in connection with the operation of tracheotomy, which, although very unsuccessful at first, is at present a measure of acknowledged utility in Holland, the fatal results in many cases being now attributed to the fact that the operation was not performed early enough. Unfortunately for the interests of medical science, Dr. Korteweg comprises under the head of "croup" both diphtheria and laryngitis, and, indeed, he appears to consider the former only an aggravated stage of the latter. Although he gives copious tables of death statistics from Amsterdam and many other Dutch localities, in which croup and diphtheria are classed in different columns, he adduces no evidence whatever to show why a distinction between them should be drawn. He insists very strongly on the influence of weather in the production of croup, and gives statistical tables showing the prevalence of the disease in the cold months of the year. It is evident, however, that the complaint he thus refers to is the ordinary laryngitis of children, which occurs in all countries and at all times, but more especially in cold weather. Diphtheria, on the other hand, is an exceptional disease, capricious in its visitations, occurring at intervals with great violence, attended with fearful mortality, often assuming an epidemic form, eminently infectious and contagious, but uninfluenced, as it would appear, by weather, or locality, or other ordinarily recognizable causes. From the want of this distinction the Dutch statistics regarding croup are of very little value, except as showing that during an epidemic of diphtheria the returns under the head of "croup" are very much augmented. The same want of distinction between common croup (*i. e.*, infantile laryngitis) and laryngeal diphtheria invalidates all the observations made as to the necessity of tracheotomy and the results of that operation in the maladies in question, for while in the former the operation is almost always successful and generally unnecessary, in the latter, though urgently required, it is too often attended with failure even in the most skilful hands.—*Med. Times and Gaz.*, Nov. 11, 1882.

TREATMENT OF HYDATID CYSTS OF THE LIVER.—M. TERRILLON writes that puncture and exhaustion of hydatid cysts of the liver is totally inefficacious in producing a cure, even when aspiration is not prevented by the clogging of the instrument with the debris of the hydatids. Electrolysis is also of very doubtful value, and free incision of the cysts even with antiseptic precautions should only be accepted

with hesitation. There only remain two methods: one, that of Recamier, of which the method of Trousseau is only a modification, consists in forming adhesions between the abdominal and cystic walls, and then subsequent evacuation of the contents of the cyst. The other is a modification, which M. Terrillon himself suggests, of the plan pursued by Boinet and Verneuil. This consists in the introduction of a trocar of one centimetre in diameter, directly into the cyst without waiting for any adhesions to form; an elastic sound is then passed into the cyst through the opening of the trocar, which is then withdrawn, leaving the sound in place. When the entrance of the fluid into the peritoneal cavity is feared, the trocar may be left in position for three or four days so as to allow adhesions to take place before introducing the sound. The author has treated four cases successfully in this manner.—*Journ. de Méd. de Paris*, November 18, 1882.

Intraorbital Aneurism.—Mr. Walter E. Lloyd reports the case of a traumatic intraorbital aneurism occurring in a pregnant woman, in whom the carotid artery was ligated one week after delivery. The wound healed well, but no change was produced in the aneurism; the eyeball was subsequently successfully extirpated.—*Lancet*, November 11, 1882.

Hemichorea after Lightning-stroke.—Greidenberg records (*Vratch*, 1882, Nos. 10 and 11) an interesting case where a telegraph clerk—a woman, aged 38—was struck by lightning on her left hand when she was engaged in closing the circuit during a thunderstorm. Having recovered from the shock, the patient found a small burnt spot on her left little finger, but felt no pain. Within a fortnight after the accident, constant movements in her fingers developed, which, some months later, spread over the whole upper limb, and, still later, over the whole left half of the body. Dr. Greidenberg, who saw the patient eight months after the accident, recognized a typical case of hemichorea, the movements being most intense in the upper limb, which was considerably wasted, and showed considerable loss of muscular power. The treatment consisted of daily galvanization, one pole being applied first to the spine, afterwards to the median nerve; another to the left brachial plexus. After five sittings of ten minutes' duration, and with the current from twenty elements, there began a decided improvement, which proceeded without interruption. After fourteen sittings the movements continued in the fingers only, and very soon the patient recovered so far as to be able to work with both hands, to embroider, etc. About three months later she returned to her professional occupation. The only traces left of the hemichorea were extremely slight motions in the fingers, controlled by the patient's voluntary efforts; slight tremor of the limb when raised; and, lastly, the burnt spot on the little finger, which had not healed, though more than a year had elapsed. —*London Medical Record*, Nov. 15, 1882.

Iodoform in Ocular Diseases.—As a contribution to the subject of iodoformania, to which we have frequently alluded, we append the following conflicting experience, taken from the *Wiener Med. Woch.* (No. 41). Iodoform, as finely powdered as calomel, and also in the form of an ointment (one part of iodoform to ten of vaseline), has been used in Leber's clinic. The healthy conjunctiva tolerates both the ointment and powder. An eye that is slightly inflamed only endures the preparations in moderate quantity, whilst free application increases inflammation. Some eyes cannot stand iodoform at all, though this is rare. Iodoform is used with the greatest benefit in recent wounds of the globe or lids, whether accidental or from operation. In the various forms of ophthalmia it is valueless. In association with boracic lint dressing the preparation does good in cases of spreading ulceration of the cornea. Another benefit conferred by iodoform is relief from pain. Grossmann got good results from the use of iodoform only in profuse suppurations—in gonorrhœal ophthalmia and ophthalmia neonatorum (P. Smith confirms this observation). Dr. Lange, of St. Petersburg, on the contrary, treated six cases with no good, but rather harm. The chief danger resulted in cases of granular lids, which became much more exuberant, and, filling up the conjunctival sac, endangered the nutrition of the cornea. Lange cautions against its use in ophthalmia neonatorum, and Hirschberg teaches that there is no reason whatever to set aside the use of the trustworthy lapis divinus. Fischer believes that iodoform is tolerated well in most ocular diseases; it is very effectual in cases of scrofulous corneæ; it is an excellent antiseptic; it promotes granulation and rapid regeneration of corneal epithelium; it is of value in lachrymal abscess with discharge.—*Medical Times and Gazette*, November 18, 1882.

Cystic Tumor due to a Hair which had Penetrated the Eyeball.—At the meeting of the Baltimore Academy of Medicine held Nov. 7, 1882, Dr. J. J. Chisolm reported a rare case of cystic tumor of the iris occurring in a child four years of age. Nine months since he was accidentally struck in the left eye by a piece of wire from a hoopskirt. It cut the cornea on the nasal side, leaving a cicatrix extending from the pupillary border to the inner corneal margin—not passing over into the sclera. The iris was adherent to the corneal wound, leaving the pupil free, however, and sight was not destroyed. Three months since, and six months from the receipt of the accident, a minute yellow spot was detected in the centre of the temporal side of the iris, midway between the pupillary border and the corneal margin. It caused no pain, and did not inject the eye. For three months its slow growth had been watched till it attained the size of a millet seed. It was considered a dangerous development, needing a special interference. The patient was brought to him for the removal of the growth. Under chloroform an iridectomy was successfully performed, removing the entire tumor with a margin of healthy iris. When the specimen was held up in the iridectomy forceps for inspection, much surprise was occasioned by finding a hair sticking directly out of the growth, and which was apparently the cause of the new development. This hair had no hair-bulb, and had not grown, therefore, in the eye, but had evidently been carried in from without at the time of the accident. It was a transplantation into the iris from which, by long-continued irritation, the growth had developed. In at least 30,000 eye patients which Dr. Chisolm has from time to time had under treatment, this was the first iritic tumor that he had met with in his practice. The child did well from the operation.—*Maryland Medical Journal*, December 1, 1882.

Xanthoma Tuberosum.—At the meeting of the Pathological Society of London, held on November 7th, Mr. Malcolm Morris showed a living specimen of a very rare skin disease which he called xanthoma tuberosum. The patient was a married man, aged forty-eight, who was suffering from saccharine diabetes. There was no history of syphilis or rheumatism; no jaundice or evidence of disease of the liver. He complained of sleeping badly, and of dimness of sight with occasional mists before his eyes. There was distinct anæsthesia of the soles. Heart weak; reflexes normal. The eruption appeared suddenly, first on the outer side of the thigh, then spreading to the trunk, to between

the fingers, and on the mucous membrane of the mouth. It consisted of small, rounded, firm, pink tubercles, with depressd centres which had more of a fawn-color in the centre. Many of the papules had disappeared since the case first come under his care. With the patient's consent he removed one of the growths and examined it microscopically. This showed small nodules in the corium, with a delicate fibrous intercellular matrix; towards the centre the fibrous tissue became more compact and firm. The superficial epithelial cells were normal. There was no connection with any glandular structures, and the older papules contained no bloodvessels. In one place he found a collection of round cells about a vessel, and he suggested whether this might not be the real origin of the growths—the tissue ultimately contracting and so causing degeneration of the cells. This case differed from those of xanthelasma in many respects, chiefly in its association with diabetes and not with jaundice; the sudden onset of the rash, and its rather rapid disappearance, and in the fact that the eyelids were not implicated. But on the other hand it closely resembled two cases, one of which had been recorded by Drs. Gull and Addison, the other by Dr. Bristowe. The three cases were all in men; they all had diabetes, they all affected the same locality and avoided the same parts; in all the rash appeared suddenly, and gradually, but rather rapidly disappeared. To these exceedingly rare cases the name of xanthoma tuberosum had been applied.—*Lancet*, November 11, 1882.

PERFORATION OF ARTERIES IN PURULENT COLLECTIONS.—At the meeting of the Société de Chirurgie, of Paris, held November 8, 1882, M. MONOD made a report on a communication of M. Bouilly in reference to the perforation of arteries in purulent collections. A man suffering from osteo-myelitis of the femur had a collection of pus in the lower part of the thigh; its incision showed that the popliteal vessels were laid bare in the cavity of the abscess. Carbolized dressings were applied; two weeks later hemorrhage occurred, which was controlled by pressure and subsequent ligation of the femoral artery. Two days later the patient was found dead in his bed. The autopsy revealed a perforation in the popliteal artery, evidently caused by ulceration from the generally reduced condition of the system.—*Gaz. Hebdomadaire*, Nov. 7, 1882.

A NEW DISEASE OF THE LYMPHATICS.—At the meeting of the Pathological Society of London held Nov. 21st, DR. GEORGE HOGGAN exhibited a number of microscopical specimens of a condition of the lymphatics of the skin, which he had not seen described, and which he believed was related to elephantiasis and angioma; it most nearly resembled a disease described by Kaposi as *lymphangioma tuberosum multiplex;* but he was doubtful whether that was a disease of the lymphatic system at all. The specimens were made from a portion of skin excised from a young boy, who had been a patient of Dr. T. Colcott Fox; they showed a very great increase in the number of the lymphatics, without any other abnormality. To the naked eye, the skin showed a number of small vesicular bodies, about the size of a split pea, which could be distended by passing the hand over the leg against the current of the lymph. The boy had suffered from severe attacks of pain in the legs; and, after each attack, the skin of the leg became more and more thickened and enlarged. The whole of the dermic tissue was penetrated in every direction by the enlarged lymphatics. Dr. Hoggan thought the case probably showed an early stage of a condition which would ultimately result in elephantiasis.—Dr. Pye-Smith inquired whether the condition was congenital.—Dr. Thin complimented Dr. Hoggan on the excellence of his preparations. He was not prepared to accept the suggestion that this case represented an early stage of elephantiasis, which he believed was due to organization of imperfect fibrous tissue about the lymphatic vessels, and not, as here, to an increase in the number of the vessels.—Dr. Hoggan could not say whether the condition was congenital or not. In the main, he agreed with what Dr. Thin had said.—*British Medical Journal*, November 25, 1882.

LIGATURE OF THE COMMON CAROTID.—At the meeting of the Society of Physicians in Vienna on October 20, Prof. Weinlicher showed a man, aged fifty years, on whom he had successfully tied the left common carotid artery for bleeding into an abscess in the left tonsil. The abscess was the result of repeated injections of an ethereal solution of iodoform into a spindle-celled sarcoma, which had grown in the tonsil and neighboring lymphatic glands. Sixteen injections had been made into the new growth from the mouth and fourteen from the neck. The solution used was of the strength of one part of iodoform to ten of ether; of this two to three minims were employed each time. This method of treating the sarcoma was practised because the patient had determined that no operation for extirpation should be performed. This case is of interest when taken side by side with a somewhat similar one reported at a recent meeting of the Clinical Society of London, in which Mr. Pepper secured the common carotid for hemorrhage into an abscess in the throat, the result of scarlatina. The Vienna patient also recovered completely from the operation. It is not stated whether antiseptic dressings were employed. It would appear that the use of antiseptics is a point of great importance in bringing about a successful result, the liability to secondary wound diseases, especially profuse suppuration, and to secondary hemorrhage being greatly lessened.—*Medical Times and Gazette*, November 18, 1882.

A NEW STAINING FLUID FOR SECTIONS OF THE CENTRAL NERVOUS SYSTEM.—PROF. WEIGERT, of Leipzig, proposes the following plan of staining sections of the central nervous system after hardening in bichromate of potassium: The sections are first stained for several hours in a concentrated watery solution of acid fuchsin, then washed in water, and then placed for a few seconds in a solution of alcohol rendered alkaline by adding to 100 c.c. of absolute alcohol 10 c.c. of a one per cent alcoholic solution of caustic potash. As soon as the first signs of the gray nerve-tissue becomes evident the sections must be removed from this fluid, washed in water, and then placed in absolute alcohol saturated with chloride of sodium; they are then cleared with oil of cloves, and mounted in balsam. By this method of staining the medullated nerve-fibres of the medulla, pons, and cord stand out as brilliant red lines or points, from a partial staining of the medullary sheath; the ganglion cells and connective tissue stain blue, the shade being deepened by immersion in dilute hydrochloric acid, one to five, and then into water, before placing in alcohol.—*Centralb. f. d. Med. Wissen.*, October 21 and 28, 1882.

WARM WATER IN JAUNDICE.—MOSLER has employed with success the injection of a large quantity of warm water into the large intestine in catarrhal jaundice. The experiments of Röhrig have shown that such injections have the effect of increasing, for a considerable time, the secretion of bile; and Peiper showed that the bile was thus rendered more diffluent. While the amount of water in the bile was increased, that of solid matter was lessened. About six hours after the injection, the solids rise above the normal, and the water falls below it.—*Lancet*, November 25, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, DECEMBER 16, 1882.

SHORT-WEIGHT QUININE PILLS.

IT is scarcely necessary to call attention to the results, as presented in this number of THE NEWS, of the analyses made of the quinine pills manufactured by the leading pharmaceutists of the country. Nothing is more important to the physician and his patients than accuracy in the preparation of the medicines which he prescribes, and so large a portion of the remedies most in vogue are now put up on a large scale in the form of granules and pills, and furnished in a shape ready for dispensing, that it becomes a matter of the utmost moment to the public that the profession shall be justified in placing confidence in the purity and accuracy of the remedies on which the welfare of a confiding community depends. In pursuance of its mission to neglect nothing which bears upon the interest of the profession, THE MEDICAL NEWS has undertaken to examine the important article of quinine pills, as furnished by a number of the leading houses of the country. Every precaution has been observed to preserve the strictest impartiality and to obtain the most perfect accuracy as to results. The analyst is one of our most distinguished experts, and the arrangements were such that he could have no knowledge of the source from which the several specimens were obtained. We believe, therefore, that the results which we publish to-day may be implicitly relied upon.

Those results are by no means pleasant to contemplate. While it is a satisfaction to find that all the several samples of quinine pills were free from adulteration, that satisfaction is greatly diminished by the fact that all the samples but two were found to be sensibly deficient in quantity, the deficiency ranging from five to about twenty per cent. If this deficiency is constant, as our examination would seem to render probable, we have here a wrong committed upon the public, against which it is the duty of the profession, as the guardians of the public health, to record its emphatic protest.

It is to be hoped that this carelessness—to use no stronger term of reprobation—does not obtain throughout the whole of the extensive list of drugs which are now thrown upon the market so plentifully in a finished state. That giving short weight is not necessary to the successful conduct of pharmaceutical manufacturing is evident from our tabulated results, which show that the houses giving the best measure are not among the least successful in the competition of trade.

SHOULD NOT THE OFFICE OF CORONER BE ABOLISHED?

IN England the office of coroner has existed for a thousand years. In France, Germany, and indeed generally on the continent of Europe, there never has been any coroner. The last statement disposes practically of at least one doubt that instantly arises in the conservative mind on asking our question. Because the coroner is an outgrowth of a mouldy past is no reason that he should flourish to-day. If he does not fulfil his purpose, he should be abolished. Let us then look squarely at the facts.

And, for example, what is the condition of the law in this State? Curiously enough in Pennsylvania and in Louisiana, there never has been any formal repeal of the old English law on this subject, so that it is binding upon us, except where it has been altered by specific statutes. We have carefully looked into the laws relating to the coroner in this State, as recorded in Dr. J. G. Lee's *Handbook for Coroners*, and we find plenty of law as to the election of the coroner, his bond, commission, dereliction, or neglect of duty, etc., but not a word as to what his duty is, except as to the coroner of the City of Philadelphia, which law we quoted in our issue for November 25th. How he is to discover his duties from existing legal provisions we can scarcely see. In Luzerne county he is directed *not* to hold an inquest except in cases of violence or suspicion, and in Philadelphia not to hold an inquest on prisoners except in certain cases. What his duties *are* he must learn from custom, common report, and old English law. His jury is fixed at six; but no law requires him to take charge of money or effects found on the persons of those on whom inquests are held. Nor do we believe that even in Philadelphia can he legally hold an inquest on the body of any infant the victim of an abortion, provided the infant was still-born. The law says he shall hold an inquest "on the body of any deceased person, etc."

Now in the *Boston Medical and Surgical Journal*, Vol. CIII. page 200, Dr. Holt examines most carefully the meaning of the words "dead body of a person," and reaches the conclusion that a fœtus only becomes a "person" after birth, and that birth is the extrusion of the entire body from the mother. If, then, a child dies, even after having breathed, but before complete extrusion from the mother, it never has become a "person," and so cannot be the subject of an inquest. How serious a defect this is in the law, the frequent practice of abortion shows only too well.

Provision was made in 1848, for *post-mortem* examinations in Berks and Luzerne counties, and down to 1867 the provision was from time to time extended to only five other counties in the State, while meantime in 1856, it had been repealed as to Berks county itself. In six counties from the year 1852 to 1871, the coroner was authorized to appoint any number of deputies he might see proper. In Philadelphia, one of the six, he has this right, and he might if he choose appoint several deputies at a salary of $2,500 each.

The salaries both of the coroner and of the deputies are paid out of the fees, and if the fees do not amount to the salary it is curtailed accordingly. What a sore temptation this is to multiply inquests unnecessarily! And we showed in our issue before alluded to that it was a temptation frequently yielded to. Many such inquests have been held, and they not only *make* the fees of the coroner amount to the sum fixed by law, but they put the county to unnecessary expense for jury fees, witness fees, hauling of bodies, *post-mortems*, etc. Thus the law is shown not only to be uncertain and loose, but inadequate in its provisions, variable in different counties in the State, and of such a character as to be a direct invitation and inducement to wrong.

Next, as to the qualifications of the coroner himself, our present system is an absurd relic of the past. At one time he was not only coroner, but a conservator of the peace, a prosecutor of crimes, a sheriff's lieutenant, an inspector of weights and measures, and a revenue officer of the crown. Now he is only a coroner, and in certain cases interchanges duties with the sheriff, either officer in case of incapacity or death of the other acting as his substitute. But as coroner alone he has double and really incompatible functions. He has to be both a skilful physician and an expert lawyer, familiar with the anatomical and pathological appearances indicating death in all its multifarious phases—by drowning, by abortion, by compression of the brain, by disease of the heart, by sunstroke, by poisons of all sorts, by alcohol, by consumption, by gunshot wounds, by compound fractures, by blood-poisoning, by asphyxia, by accidents of all kinds, and we must even add an "etc." And with all this he must know the law from beginning to end, the old English common law as a guide to what his legal duties are, the later statute law of both the mother country and of this State to know how his duties may have been limited or enlarged, the laws pertaining to murder, manslaughter, self-defence, responsibility for accident, commitment and detention of criminals, besides other endless details of which we ourselves are ignorant.

We doctors can readily imagine what a mess a lawyer would make of an autopsy, or of a medical diagnosis, and a lawyer can readily see how a doctor would come to grief in the management of a case at law. We can readily see then that the poor coroner who must be both, is almost certain of impalement on either one horn of the dilemma, or often on both. If a doctor, the legal horn is pretty sure to gore him; if a lawyer, the medical horn wounds; if neither doctor nor lawyer, ten to one he will be tossed by both. Medical knowledge is more requisite than legal, and hence, as Mr. Wakley so pertinaciously and so successfully urged in the *Lancet* a half century ago, the coroner under present regulations should be a doctor rather than anything else, but even this is only the least of several evils, as we have shown. Even when the coroner has been a physician, the deputy, who generally does more than half the work, has never been a medical man.

Of the practical workings of the present system and of the remedy, we shall have something to say hereafter.

"PNEUMO-URIA."

IN another column we give a very interesting paper and discussion on Pneumo-uria, that is, a discharge of gas along with the urine. DR. KEYES has rendered an important service in recording two cases of such rarity that neither he nor Dr. Van Buren has seen any other within the last fourteen years, and of which he has only found two recorded cases. In the discussion four or five other cases are added to the list, but it is to be especially noted that these were all from decomposition of the blood-clots of hæmaturia. Dr. Keyes' cases are of a different class. They are not from vesico-intestinal fistulæ; they are not from decomposition of the urine, for they coexist usually with clear, sweet, normal urine. Sometimes the urine may be putrid when sulphuretted hydrogen is found in addition to the ordinary gas, but a little of such ill-smelling gas goes a long way. Indeed, we suspect that much of it would be dangerous to life.

In women, Matthews Duncan speaks of such an escape of air from the bladder as nothing unusual,

but attributes it, as does Goschler, to its previous admission by the catheter. Marie (*L'Union Médicale*, 1865, p. 55) also relates a very interesting (and amusingly told) case in which prolonged "vesical sonorities" accompanied dysuria. On passing a catheter, he was so fortunate as to open freely an old abscess which had been the source of the gas. The operation was followed by complete and speedy recovery.

We see frequently that liquids in other closed cavities undergo decomposition with the production of gas, as in abscess-cavities, in the pleura, and even in the arachnoid. Morgagni also mentions one case in which the gall-bladder was empty of bile, but distended with air. But in these cases, as a rule, the gas is offensive, as is natural from its origin by decomposition. The source of an inodorous gas found in the bladder is very doubtful. In cases in which the catheter is in constant and frequent use, it is most likely from without. Air so introduced may remain for a considerable time without absorption, and from time to time a part of it may be expelled with the urine. Whether air can also be secreted by the bladder is a question as yet unsolved. Certainly, Mallez is wrong in saying its escape is "not uncommon." We hope that the publication of this paper will call attention to the subject and elicit other cases from neglected records.

THE INFLUENCE OF THE SPLEEN ON DIGESTION.

TWENTY years ago, Schiff claimed that extirpation of the spleen in dogs entirely destroyed the normal function of the pancreatic juice of digesting albuminoids; but neither his theories nor the data on which they were based have been accepted as conclusive or reliable. The discovery by Heidenhain in the granular contents of the pancreatic cells of *zymogen*, as the substance which is converted into trypsine, the proteolytic ferment of the pancreatic juice, seemed to further justify the denial of any exterior influence to the digestion of proteids by the pancreas.

HERZEN, in a recent communication to the *Revue Scientifique* for November 25, has again opened the question and reports some experiments which seem to support the views first advanced by Schiff, and which he also advocated in a paper published in 1877. He claims that while zymogen is being continually formed, even in animals deprived of the spleen, it is never (though this statement has been denied by Mosler) converted into trypsine after extirpation of the spleen, and its conversion into trypsine is proportional to the degree of splenic dilatation. It is accordingly claimed that the spleen in the dilatation to which it is subject during gastric digestion, elaborates a ferment which is conveyed to the pancreas and converts the zymogen into trypsine, and that the presence of this ferment, at least in the living pancreas, is a *sine quâ non* for the transformation of zymogen into trypsine, though out of the body such metamorphosis may occur from mere oxidation.

To put this view to the test of experiment, Herzen killed two dogs, one in full digestion, the other after having fasted twenty hours; an infusion in a five per cent. solution of boric acid was then made of the spleen of the digesting and of the pancreas of the fasting dog; either solution alone was incapable of digesting albumen, but a mixture of the two possessed active digestive powers, while a mixture of splenic and pancreatic infusions of the fasting dog was entirely inactive. Although these experiments are not reported in detail, they certainly seem to indicate some connection between the spleen and the pancreatic digestion of albuminoids. We must confess that—although we know of no experimental support for the statement—the known readiness with which zymogen is converted into trypsine in the presence of a dilute acid, suggests the possibility of its conversion during life into trypsine in the presence of an acid formed in the pancreatic cell under circumstances similar to what occurs in the muscle cell during its functional activity.

THE NEW YORK COUNTY SOCIETIES AND THE NEW CODE.

THE very proper action of the thirty-four New York county societies which have already instructed their delegates to the next State Medical Society meeting, to vote for the repeal of the New Code, seems to foreshadow its fate with almost certainty. This appears, however, to have worked the *Medical Record*—the apostle of the New Code—into a rather unamiable mood, and in apparent despair it calls the delegates ugly names, and, likening them to dogs, says that they go to the "annual gathering with collars about their neck, engraven with their master's stamp."

Delegates are appointed to represent constituents, and when constituents have decided views on a subject they are quite right in making them known. But the advocates of the new Code do not want to learn professional sentiment. Had they, they would have last year adopted Dr. Squibb's honorable motion to postpone action on the Code until the next meeting, so that it could be ascertained. Then *they* had the meeting "fixed," and they would not postpone action for even a day, but they rushed through their revolutionary Code on the first day of the meeting, and on the day on which it for the first time saw light.

It now remains to be seen if, after a thorough discussion of the subject, the advocates of the new

Code will gracefully yield to the declared will of a very large majority of the profession of their own State, and in deference to the sentiment of the whole profession of the rest of the United States, as formally expressed with absolute unanimity by the American Medical Association, and by the State medical societies from Maine to California.

The large delegation from the New York County Medical Society has been carefully selected by the originators and supporters of the new Code, and they are pledged to attend the annual meeting of the State Society, and to vote to sustain the new Code. At a slimly attended meeting like last year's, it would almost be within their power alone to prevent its repeal. It is therefore extremely important that all the county societies should be represented by full delegations, and that the permanent members should, as far as possible, be present at the ensuing meeting in February.

Whatever the final result may be, we hope the yeas and nays will be demanded, so that the profession of the State and of the country at large may know who of their honorable calling are so forgetful of the standard of professional morals as to be willing to consult with charlatans, and, by thus affiliating with them, to commend them to the respect and confidence of the community.

ESERINE AND ATROPINE.

RECENT observations in ophthalmic practice have confirmed, in a most notable and exact manner, the results of the experimental study of eserine and atropine. The antagonism of actions existing between these agents, is one of the most striking exhibitions of this principle in the whole series of physiological antagonisms. There is a notion abroad in the medical profession, that the demonstration of an antagonism in animals, cannot be applied to the same conditions in man; much less, can the knowledge thus obtained be utilized in the treatment of man's diseases. Besides the large amount of experimental and clinical evidence, to which we might call the attention of our readers, there were published in the issue of the *Lancet* for November 11, two cases of eye disease which perfectly illustrate the success with which the physiological study of eserine and atropine has been applied to therapeutical problems. In the first case, the condition of the eye was that of intermittent glaucoma, with increased intra-ocular pressure; in the second, there was recurrent iritis, with increased intra-ocular pressure. The myositic, eserine, a pupil contractor, relieved the former; the mydriatic, atropine, a pupil dilator, was successful in the latter. Notwithstanding the increased tension of the eyeball, in both cases, remedies acting oppositely succeeded; and not by haphazard empiricism, but by the accurate adaptation of scientific principles.

THE ONTARIO HEALTH BULLETIN.

THE weekly health bulletin issued by the Provincial Board of Health of Ontario is a sheet about the size of the daily weather chart of our signal office, and consists of an outline map of the province, which, for the purposes of the statistician, has been divided into ten districts. The bright colors with which these districts are overlaid are suggestive of an attempt to indicate the prevalence of disease by their means, but on closer examination it is found that they only serve the purpose of showing the divisions. The six diseases which have been most prevalent in each district during the week are printed in the order of prevalence on or near each division, while a graphic delineation of the comparative area of prevalence of each of the diseases which have figured as one of the first six in one or more of the districts is given in one corner, and a similar delineation, with an attached scale, enables the degree of prevalence of each disease to be compared. But the reader wants naturally to know on what data the official announcements are made. As a health bulletin, we are inclined to prefer Dr. Baker's statements of prevalence in Michigan, as observed by so many medical men in different parts of the State.

THE NEW PENAL CODE OF NEW YORK STATE.

ON December 1st, the New Penal Code of New York State went into operation. As two or three of its provisions affect the medical profession directly or indirectly, we call attention to them.

It behooves physicians in that State to be watchful of their habits and prescriptions, for it is provided that any physician who, while intoxicated or by mistake, gives any drug to his patient in such dose as to kill, is guilty of murder in the second degree.

"A person," says section 305, "has the right to direct the manner in which his body shall be disposed of after his death, and direct the manner in which any part of his body which becomes separated therefrom during his life-time shall be disposed of." Under such a law Dr. Weir Mitchell's soldier-hero, George Dedlow, could have claimed his legs from the Army Medical Museum.

It is made a crime to attach a dead body for debt or to obstruct or detain a funeral. Many other provisions seem to us to be excedingly wise. Duelling, cruelty to children and to animals, overloading of vessels with passengers, carelessness as to steam boilers, are all made punishable; the care and preservation of life, generally, is provided for most commendably.

We observe also that the law as to the responsibility of the insane, idiotic, and imbecile, requires that it must be proved that he was laboring under such a defect of reason as either not to know the nature and quality of the act he was doing, or not to know that the act was wrong. A morbid propensity to commit prohibited acts existing in the mind of a person who is not shown to have been incapable of knowing the wrongfulness of such acts, forms no defence to the prosecution therefor. We wish the "New York Code" in medicine were equally as wise.

IN the *Philadelphia Inquirer* of December 5 is a statement the like of which we never remember to have seen before. Twenty cases had been reported to the Coroner on the preceding day, of which *eight were referred back to the physicians as unsuitable cases for inquests*. We hardly expected that our editorial defining the relations of physicians and the Coroner, published a few days before, would bear such speedy and such abundant fruit. Moreover, we congratulate the County and the Coroner on the resulting saving, which for that day alone would be not far from one hundred dollars—a very fair gain for one day.

SPECIAL ARTICLE.

THE MEDICAL NEWS COMMISSION

ON THE

COMPOSITION OF PHARMACEUTICAL PREPARATIONS.

QUININE PILLS.

IT is of the highest importance to the profession and to the public to know if the pharmaceutical preparations which are prescribed and purchased are what they are represented to be both in quality and quantity; for it is very evident to the most casual observer that neither temptation nor opportunity is lacking to those who may be willing to adulterate their preparations and dispense them in short measure.

Of all the drugs in the Pharmacopœia, quinine is probably one of the most largely used and at the same time one of the most expensive. As there is an immense demand for it everywhere, and as there are considerable difficulties in the way of both physicians and patients ascertaining the precise amount of quinine in a pill, owing to the presence of excipients and coatings, and equally great difficulties in the way of detecting adulterations, it is readily seen that the manufacture of quinine pills offers a most attractive field to any pharmaceutist who is disposed to take advantage of his opportunities.

The leading manufacturing pharmaceutists have for some years found it profitable to make for the trade, on a very large scale, the pills which are in common use, and the retail apothecaries, as a rule, keep these pills in stock and dispense them as a matter of convenience, and because they can be sold at a lower price than those which are made on a small scale by hand.

With the view of ascertaining how well the public is served by the leading manufacturing pharmaceutists THE MEDICAL NEWS instituted an investigation as to the purity and weight of the pills made by them, and two-grain sulphate of quinine pills were, for obvious reasons, selected for the test.

In the middle of October, THE MEDICAL NEWS purchased in unbroken packages from seven of the largest manufacturers, or from their agents, bottles, each containing by actual count, 100 two-grain sulphate of quinine pills. The pills were then put in new bottles, numbered respectively 1, 2, 3, 4, 5, 6, and 7, and placed in the hands of an expert analytical chemist, to ascertain the amount of the alkaloid contained in each pill and its purity, without his having any knowledge, indication, or clue as to who were the manufacturers of the different specimens. To eliminate all possible errors, a second series of analyses, and, where these showed any discrepancies, a third series were made under the above conditions, the numbers, however, being varied in each series, for evident reasons.

METHOD OF ANALYSIS.

The analysis was conducted by the following method: 20 pills were dissolved in distilled water, by the aid of a little dilute sulphuric acid, and, in the case of the sugar-coated pills, the solution filtered, in order to remove starchy matter, etc., and the filter thoroughly washed with water. The resulting solution was then super-saturated with ammonia water, and the precipitated alkaloid dissolved by agitation with successive portions of pure ether until, after the separation of the ether, the remaining aqueous liquid no longer gave any reaction for an alkaloid with potassio-mercuric iodide; thus affording evidence of its complete abstraction. The ethereal solution was first allowed to evaporate spontaneously in a weighed glass capsule, then dried at 100° C. (212° Fah.), and finally dried at 125° C. (257° Fah.), until the weight remained constant.

Seven specimens of pills were thus examined, with the following results.

SERIES I.

No. I. (compressed). Two-grain bisulphate of quinine pills. Average weight of each pill, 2.07 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill 1.24 grains; corresponding to crystallized bisulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *2.10 grains*.[1]

No. II. (gelatine-coated). Two-grain sulphate of quinine pills. Average weight of each pill, including coating, 3.48 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.31 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.76 grain.*

[1] The small excess of quinine obtained in this instance is doubtless due to the employment of a slightly effloresced salt.

No. III. (sugar-coated). Two-grain sulphate of quinine pills. Average weight of each pill, including coating, 5.14 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.48 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.99 grain.*

No. IV. (sugar-coated). Two-grain sulphate of quinine pills. Average weight of each pill, including coating, 4.69 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.199 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.61 grain.*

No. V. (sugar-coated). Two-grain sulphate of quinine pills. Average weight of each pill, including coating, 5.16 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.323 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.78 grain.*

No. VI. (sugar-coated). Two-grain sulphate of quinine pills. Average weight of each pill, including coating, 4.34 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.269 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.71 grain.*

No. VII. (gelatine-coated). Two-grain sulphate of quinine pills. Average weight of each pill, including coating, 3.05 grains. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.42 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.91 grain.*

All the specimens were found to be free from the associate alkaloids of quinine, viz., quinidine, cinchonine, and cinchonidine, and to respond to the official tests of sulphate of quinine for identity and purity.

Owing to the deficiency in weight of five of the above examined specimens, a second analysis was made of newly purchased samples, which were similarly numbered 1, 2, 3, 4, and 5; the numbers, however, not corresponding to those attached to the first set of specimens submitted. The analysis was performed in the manner above described, and afforded the following results:

SERIES II.

No. I. (sugar-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.39 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.87 grain.*

No. II. (sugar-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.26 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.70 grain.*

No. III. (gelatine-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.424 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.91 grain.*

No. IV. (sugar-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.318 grain; corresponding to crystallized sulphate of quinine $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.77 grain.*

No. V. (gelatine-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.308 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.76 grain.*

SERIES III.

No. I. (sugar-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.26 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.70 grain.*

No. II. (sugar-coated). Two-grain sulphate of quinine pills. Average amount of anhydrous quinine, $C_{20}H_{24}N_2O_2$, obtained from each pill, 1.42 grain; corresponding to crystallized sulphate of quinine, $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$, *1.92 grain.*

TABULAR STATEMENT OF THE RESULTS.

For convenience of comparison the results are arranged in tabular form.

Manufacturer.	Series I.		Series II.		Series III.	
	No.	Grs.	No.	Grs.	No.	Grs.
John Wyeth & Bro., Philadelphia.	I.	2.10				
McKesson & Robbins, New York.	II.	1.76	V.	1.76		
Bullock & Crenshaw, Philadelphia.	III.	1.99				
Wm. R. Warner & Co., Philadelphia.	IV.	1.61	II.	1.70	I.	1.70
Parke, Davis & Co., Detroit.	V.	1.78	IV.	1.77		
Keasbey & Mattison, Philadelphia.	VI.	1.71	I.	1.87	I.	1.92
W. H. Schieffelin & Co., New York.	VII.	1.91	III.	1.91		

RELATION OF THE PRICE OF QUININE PILLS TO THE AMOUNT OF QUININE THEY CONTAIN.

As a matter of collateral interest, it is worth while to consider the varying price at which the two-grain pills are furnished, and the relation of the price to the amount of quinine they contain. This is shown in the accompanying table, in which are given the current retail prices which were paid by THE MEDICAL NEWS for the specimens purchased for the first series of analyses.

Manufacturer	Quinine per pill.	Price per 100.
John Wyeth & Bro.,	2.10 grains.	$ 2.50
Bullock & Crenshaw,	1.99 "	2.30
W. H. Schieffelin & Co.,	1.91 "	2.75
Parke, Davis & Co.,	1.78 "	1.70
McKesson & Robbins,	1.76 "	1.76
Keasbey & Mattison,	1.71 "	1.90
Wm. R. Warner & Co.,	1.61 "	2.75

The range we found to be from $1.70 (the lowest) to $2.75 (the highest) per hundred—a variation of 60 per cent.; and there is no constant relation between the price of the pills and the quantity of quinine they contain.

THE GENERAL RESULTS OF THIS INVESTIGATION.

From the foregoing facts we learn:

I. That the quinine pills of five out of seven of our leading manufacturers have not in them the amount of sulphate of quinine which they are represented to contain.

II. That there is a great variation in the price at which the pills can be purchased.

III. That the price bears no relation to the amount of quinine really contained in the pills.

REVIEWS.

ON SLIGHT AILMENTS: THEIR NATURE AND TREATMENT. By LIONEL S. BEALE, M.B., F.R.S. Second edition. 8vo. pp. 283. Philadelphia: P. Blakiston, Son & Co., 1882.

"What is here?
Gold! yellow, glittering, precious gold!"

COMMUNISM has sought to diffuse equally the material riches of the globe, but the sequel has always been a revolution. Apostles of mental communism reproduce the story so well told in Addison's *Spectator*, in which an equal distribution of the hardships and misfortunes among mankind resulted in a chaos of calamity, until Jove at last returned to each his share again.

The gold of the world of thought cannot be allotted by the ton to the multitude, and books like this we fear attempt an impossibility. The instincts of the born physician direct him, and he is an empiricist only in name. Let him impart his methods and his valued recipes sink to the level of the cook book, which the born cook puts into the hands of the amateur while she still uses her pinch of salt and lump of butter as large as an egg.

The gold of good ideas is in this book, but let us rather explain in such works as these the principles of morbid pathological processes, be they slight or gross. Let us seek to meet them by the physiological action of drugs, as far as possible, and when this fails, let us stimulate original thought in this direction, letting necessity suborn the empiric's art, and constituting her the hand-maid of science. For necessity is the mother of prudent invention. We are led to comment thus, because nothing essentially new appears in this second edition. Empiricism, or experience with ignorance, is extolled. Old-fashioned purgatives, emetics, acids, or antacids find favor. Dr. Beale is sanguine about the virtues of mercurials in the cure of headache (which he considers to be developed by biliousness), and in many other conditions for which our grandmothers were wont to advise blue pill.

The table of contents includes peculiarities of the tongue in slight ailments; offensive breath; nausea; indigestion, its nature and treatment; constipation, and its treatment; diarrhœa; vertigo; biliousness and sick headache; neuralgia and rheumatism; the feverish inflammatory state; the actual changes in fever and inflammation and common forms of slight inflammation, including sore-throat, conjunctivitis, etc. etc. The remedies suggested for these derangements, without being new, are correct, and those physicians who enter practice without hospital training, will doubtless find their time profitably spent in its perusal.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, December 6, 1882.

THE PRESIDENT, W. S. W. RUSCHENBERGER, M.D., IN THE CHAIR.

DR. J. EWING MEARS read

A RÉSUMÉ OF TWENTY-FIVE CASES OF ABDOMINAL SECTION.

With a view of placing on record the results in a number of cases of abdominal section, and with the hope of contributing to the information possessed already with regard to these operations, I beg to submit the following *résumé* of the cases which have come under my care.

I have endeavored to present the points, which were regarded of interest, in a concise manner, for this purpose grouping them under different headings.

Of the twenty-five cases of abdominal section, twenty-two were performed for the removal of tumors of the ovary; one was made in a case of encysted dropsy of the peritoneum; one in a case of abdominal dropsy, in which the diagnosis was obscure, and an operation of exploration was made; and one for removal of the child in extra-uterine fœtation.

As the case of encysted dropsy has been reported to the College (See *Transactions*, 3d Series, Vol. I.), and as I propose, at a future time, to report the one of extra-uterine pregnancy, I shall present on this occasion a *résumé* of the ovarian cases.

Age of Patients.—In the twenty-two cases the age varied from the youngest, sixteen, to the oldest, sixty-five years.

Nationality.—Sixteen patients were natives of the United States, and six of Ireland.

Social Condition.—Five were single, one was a widow, and sixteen were married.

Duration of Growth.—The duration of growth varied from three months to seven years, counting from the time at which the tumor was recognized first by the patient.

Aspiration, or Previous Tapping.—Aspiration, for the purpose of obtaining a specimen of fluid for examination, was performed in eight cases; tapping, to relieve abdominal distention, in four. In one case, in which the cyst was very fully distended by fluid, and the abdominal wall was very tense, leakage followed aspiration, and persisted for some hours, despite the efforts made to control it by pressure. In none of the cases, in which aspiration or tapping was performed, did any serious results occur, nor were there any evidences in the operations, which followed, of complications due to the previous aspiration, or tapping. In all cases, proper precautions were taken, the patient being required to rest in bed from three to four days subsequent to the operation.

Condition of the Patient at the Time of Operation.—With the exception of two, who were the subjects of malignant disease of the ovary, the condition of the patients was good. All were placed upon preparatory treatment, extending over periods varying from two weeks to two months.

Line of Incision.—In all cases the abdominal cavity was opened by incision in the linea alba, midway between the umbilicus and pubes, the length of the incision varying according to the nature of the tumor and the presence or absence of adhesions. A simple,

monocystic, non-adherent growth was extracted easily through an opening one and a half inch in length; whilst other tumors, polycystic in character, with numerous and strong adhesions, required incisions from four to six inches in length, in order that the hand could be introduced into the abdominal cavity, so as to sweep over the external surface of the tumor for the purpose of detaching adhesions, and also into the interior of the growth to disintegrate its contents, and thus reduce its size. The incisions were invariably closed by the introduction of metallic sutures—iron or silver wire—the needle being carried so as to include the peritoneum.

Adhesions.—In eighteen cases, adhesions, either parietal, omental, or visceral, existed—differing greatly as to extent and character. In some instances they were so slight as to be separated readily with the finger: in others, they were very extensive and very firm, requiring some force to effect their detachment, and exposing denuded, bleeding surfaces. In one of the fatal cases the adhesions were universal, and so firm as to require a minute dissection to be made, in order to effect removal of the cyst.

In a second case, a portion of the parietal surface of the peritoneum as large as the palm of the hand, and embracing the sub-peritoneal fascia, was detached, leaving a broad band of attachment. This was included in three animal ligatures, and the detached portion removed. During the period of recovery, which was not retarded, the patient referred to the position of the exposed surface as a sensitive point. In still another case, an adhesion, in the form of a cord, at least two inches in thickness and from four to five inches in length, fastened the tumor to the parietes. It was drawn down and a double animal ligature applied before section was made. Hemorrhage caused by the separation of adhesions has been controlled by the application of carbolized silk and animal ligatures, both ends being cut short and the ligatures permitted to remain "*in situ.*" In some instances, torsion of the vessels has been sufficient to restrain the bleeding.

Character of the Cysts.—Four cysts were unilocular, sixteen were multilocular, and in two, malignant disease existed. In one of the latter medullary cancer involved both ovaries, and in the other colloid disease was present.

Double ovariotomy was performed in two cases.

Primary or Secondary Operation.—In one case the operation was secondary, ovariotomy having been performed thirteen years previously. In this instance the incision was made to the side of the cicatrix of the primary operation, so as to avoid wounding the pedicle of the tumor removed, which was found to exist as a small cord attached to the inner surface of the abdominal wall, and to be of such length as to permit the uterus to occupy a normal position. Elongation and shrinkage of the pedicle has been observed in *post-mortem* examinations made in cases in which death occurred some years after ovariotomy.

Treatment of the Pedicle.—In all but one case the pedicle was secured by the application of the clamp; in the case excepted, a carbolized catgut ligature was applied, both ends cut short, and the pedicle was returned to the abdominal cavity. In cases of very short pedicles I have been able always to secure them with the clamp, and in no case was it observed that the traction made to accomplish this produced any harm. In one instance of an extremely short pedicle, where, in fact, the wall of the cyst was separated not more than a half inch from the uterus, a double animal ligature was applied, which failed to control the hemorrhage. The clamp was then applied over the ligature, bringing the uterus well up between the edges of the incision. Although the patient had a tedious convalescence, the ligature and clamp came away in good time, and the abdominal incision healed kindly. Beneath the cicatrix the uterus could be distinctly outlined, and after the return of the patient to her usual duties no complaint was made of pain caused by traction upon the organ. In one case only was there noticed a slight tendency to the occurrence of ventral hernia, and this in a young patient who slipped and fell on the icy pavement a short time after recovery from the operation. A good deal of tension of the abdominal walls was felt in the act of falling, and it was thought a slight detatchment of the pedicle had occurred. Rest in bed for a few days, with pressure over the cicatrix, relieved the condition.

In nearly all of the cases in which the clamp was applied it was observed that it could be removed safely at about the same time with the last of the sutures, and, therefore, the healing of the abdominal incision was not materially delayed. In one or two cases both sutures and clamp were permitted to remain longer than usual. In favorable cases the first of the sutures was usually removed on the sixth day, and the clamp on the eighth or tenth.

In three cases menstruation has occurred by the pedicle. In all of the cases it took place but once, and did not produce any serious inconvenience. It occurred in one of the cases in which double ovariotomy was performed, two clamps having been applied to the pedicles without difficulty.

Strangulation of the intestine has been noted as being due to the use of the clamp. In my observation of the cases of others, and in my own, I have not met with an accident of this nature. As it has followed likewise the use of the ligature, it cannot be ascribed alone to the employment of the clamp.

The support afforded to the uterus by the attachment of the pedicle to the abdominal walls has seemed, in some of the cases, to have been of benefit, overcoming displacements which were productive of much previous discomfort.

In one of the three fatal casès which occurred, the ligature was applied and the pedicle returned to the abdominal cavity; death resulted on the third day from septicæmia, and the autopsy showed the stump of the pedicle softened and covered by a grayish slough. This condition of the pedicle was, I think, not a primary condition, but was a part of the general inflammation which pervaded the abdominal cavity, occurring in a case in which the cyst was adherent in every part to the parietes and viscera, and which required minute dissection to effect its separation.

While the tendency of the present day is to return to the use of the ligature as an exclusive method of treating the pedicle, I think it unwise to discard entirely the clamp. The imbedding of the ligature and its subsequent absorption demand a degree of reparative power, which some much debilitated patients do not possess; in such cases it would appear proper to employ the clamp.

Drainage.—In one case it was thought desirable to secure drainage of the abdominal cavity after operation. For this purpose a large perforated rubber tube was introduced and allowed to remain in position for three days. During this period no fluid escaped, and the symptoms presented by the patient gave no indication of the collection of septic fluids. Of the great value of drainage after ovariotomy there can be no question. Its use is especially indicated in cases in which adhesions of some extent have existed.

Antiseptic Precautions.—In fourteen cases the antiseptic methods were employed in full detail at the time of operation, and partially during the conduct of the after-treatment, the spray being then omitted. The

successful results which have attended some of the cases were undoubtedly due to its use. The condition of the patients during the after-treatment was favorably influenced, and convalescence was promoted. Of three fatal cases, one occurred after operation under this system. The tendency of most operators at the present time is to employ a modified form of the system, owing to the fear of constitutional impressions made by the agents employed. The constitutional effect of the carbolic acid has been observed in two or three cases in the condition of the urine; other than this no symptoms were noted.

It has been stated above that menstruation by the pedicle occurred in three cases. In one a marked impression was made upon the temperature, and the elevation, occurring as it did without being accompanied by a corresponding increase of the pulse-rate, attracted attention. On the day preceding the appearance of the flow the pulse was 84 and the temperature normal, 98½°. On the day of its appearance the temperature rose to 100°, and on the third day reached 100⅝°, then declined to 99⅗°–99°, and on the day of the cessation of the flow returned to the normal, 98½°—the pulse-rate in the meanwhile remained unchanged. As the elevation of the temperature occurred after convalescence had been fully declared, and the patient was within two days of the period when she would have been permitted to sit up, some anxiety as to the cause existed, which was not relieved until its relation to the presence of the menstrual flux was considered.

In two of the cases pregnancy occurred and terminated safely in connection with the development and growth of the cysts. In both, the cysts had attained large size, and notwithstanding the pressure exerted during parturition rupture did not occur. In one, puerperal peritonitis supervened, causing the formation of extensive adhesions; in the other, slight but firm adhesions were found.

In cases under my care recently, quinine has been administered in large doses in the twenty-four hours preceding the operation, with a view to obviate shock, and in this respect its use has been attended with success. Thirty to sixty grains, in divided doses, have been given, and in each case so treated shock has been absent. In the preliminary and after-treatment it has also been given in tonic doses.

The duration of the operation has varied from thirty minutes to two hours; in the former time, monocystic non-adherent tumors have been removed and the wound closed. The latter period of time has been required to remove polycystic growths, with extensive and firm adhesions and many bleeding points to control. Serious complications during the operation and after-treatment have occurred in but two cases. In one already alluded to the adhesions were so extensive as to complicate seriously the operation and to render the result fatal. In the other, the slipping of the ligature and the persistence of hemorrhage for some hours after the closure of the wound complicated the operation. This patient's recovery was slow, two months and a half elapsing before she was able to leave her bed, in which period there occurred in order the following complications—obstinate, uncontrollable diarrhœa, suppuration of hemorrhoids, formation of a large bed-sore over the region of the sacrum, with destruction of the sacro-coccygeal articulation, and a condition of blood-poisoning with swelling of the left parotid gland. Recovery finally took place, and the patient has been able to maintain herself by her work as a seamstress.

The size of the tumors varied greatly, and the weight from three to sixty pounds.

With one exception, all the operations have been performed either in private houses or in a private hospital. One was operated upon in a private room of a general hospital, and in this a fatal result ensued—death, however, could not be attributed to this fact, but rather to the complications which existed in the case. In all cases careful attention was given to the preparation of the apartments so that the patients should be placed under the most favorable hygienic conditions.

In the cases in which the progress was favorable the patients, as a rule, sat up in bed on the twelfth day, and on the fourteenth were permitted to get out and occupy the lounge or an easy-chair. At the end of the third week gentle exercise about the house, and, in favorable weather, in the open air was allowed. This exercise was continued daily so as to prepare the patient, if living out of the city, for the journey home, which was undertaken between the fourth and fifth weeks after operation.

For twenty-four hours after the operation no food was given—at the end of this time, one ounce of milk, with lime-water, if vomiting had occurred, or if there was nausea, was given every three or four hours. In two or three days the amount of milk was increased to two ounces every three hours, alternating with a teaspoonful of beef-juice in three tablespoonsful of water. In some cases the beef-juice was administered instead of the milk from the first. As convalescence advanced additions were made cautiously to the diet, no solid food being given until the sutures and clamp had been removed and the bowels moved freely by enemata.

Usually enemata of soap-water and olive oil were administered on the eighth day, and on alternate days, subsequently, until evacuations occurred naturally. The catheter was used every six or eight hours for five days, and then efforts at evacuation of the bladder were permitted to be made by the patient.

When possible to avoid it, opiates were not administered. When required to relieve pain or secure rest, morphia in one-sixth to one-quarter of a grain was given hypodermically.

In the twenty-five abdominal sections death occurred in four cases—three after operation for the removal of ovarian cysts, and one after operation for the removal of the child in extra-uterine fœtation. Septicæmia was the cause of death in two of the ovarian operations, and in the case of extra-uterine pregnancy. Shock and hemorrhage produced a fatal termination in the case of malignant disease of both ovaries in which double ovariotomy was performed.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 7, 1882.

THE PRESIDENT, FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

THE minutes of the previous meeting, and the usual reports of the Librarian and Corresponding Secretary were first read and approved.

DR. BARKER stated that, having acted as presiding officer of the Academy during a period of four years, he desired to make a few remarks relative thereto, pending the close of his second term of office. During his presidency the Academy has been unusually prosperous. A large number of valuable scientific papers have been read by Fellows of the Academy, extensive additions to the library have been made, and the general financial condition of the organization has been greatly improved. He said that the Academy's recent prosperity was the result of the good work which had been done before, and that he had been extremely fortunate in having been the incumbent of the chair during this particular period. In conclusion he signified his intention of not again becoming a candidate for the office of President.

The nominations for officers were next proceeded with, after which the scientific work of the evening was taken up. This consisted in a paper by ALLAN MCLANE HAMILTON, M.D., entitled,

A CASE OF MYXŒDEMA, WITH A CONSIDERATION OF THE NEUROTIC ORIGIN OF THE DISEASE.

The paper began with a brief, but careful, mention of the few cases of this new and interesting disease already reported. Myxœdema is an affection of adult life, chiefly in females. It resembles cretinism; also Bright's disease, with which it has been confounded. It usually occurs after the menopause, and in women who have been many times pregnant. The symptoms are well marked, characteristic, and more than ordinarily constant. There is swelling of nearly all parts of the body, notably of the cheeks, nose, lips, eyelids, and tongue. The legs and ankles are often enlarged. On pressure there is no pitting; the surface is tough and resilient. The part pressed upon regains its form when the pressure is removed. Sensibility to peripheral impressions is decidedly diminished. Numbness is present, and sometimes formication. The skin is altered in texture, as well as in color. There is little or no perspiration, and little response to friction or stimulation of the surface. At times there are warts and moles in various regions. The finger ends are clubbed. This, in common with many other symptoms, is apt to be more marked on the right than on the left side. The nails are brittle, and their thickness and configuration changed. The hair comes out from the axillæ and pubes, as well as the head. The thyroid gland wastes away, and fatty deposits are often made in its atrophied substance.

Lowering of temperature is a very important symptom. This tends to be more marked on the right side, which is often a degree or more lower than the left side. In a case where seventy-one observations were taken, the normal was reached in but sixteen. The temperature never exceeded 98.6°, and it fell below 97° nineteen times. It may decline to 95°, and in one fatal case it was 94° for a day or more before death. The temperature is lowered both superficially and internally; and patients complain that they feel very cold.

The mind is involved early in the disease. The first symptoms vary. There may be hallucinations, melancholy, moroseness, bad dreams, and disturbed sleep, and even mania. Later there is marked apathy. Mental processes are very sluggishly performed. The patient is forgetful, especially of recent events and trifling duties, dull of perception and comprehension, and lacks power of concentration.

The special senses are less acute, especially the hearing, taste, and smell. The sight is not often affected. The speech is slow and thick; the voice nasal, harsh, and monotonous—these changes arising from the mental inactivity, from the enlargement of the tongue, and sometimes from relaxation of the vocal cords. In some cases the saliva is very profuse; in others there is an abundant watery secretion from the nose. Sometimes the tendon-reflex is exaggerated. Electro-muscular contractility and galvanic reaction may be diminished on the left side.

There is also motor enfeeblement and derangement. The loss of power is often general, but some patients who perform great efforts with ease fail in minor matters. They are awkward in all their movements, especially those requiring delicate coöperation of several muscles, as in threading needles, buttoning clothes, writing, etc. The peculiar gait resembles the waddling of a duck.

The arterial tension is generally increased. This may be shown by the sphygmograph, though the toughness of the skin makes it somewhat difficult to get satisfactory tracings. There are rarely any heart lesions. The pulse is slow and feeble. The red blood-corpuscles are reduced in number, and especially in size, giving rise to anæmia.

Albumen is seldom found in the urine, very rarely in the early stages. The urea is diminished in amount, sometimes to two-fifths the normal quantity. This may be explained, at least partially, by the muscular inactivity. The specific gravity of the urine, as a rule, is low. Sugar has been present in but one case.

Dr. Hamilton cited a recent case of his own, presenting many of the foregoing symptoms. The patient is a woman 55 years old. She is married, and has been pregnant eight times. Her characteristic symptoms date back about eighteen months.

The speaker believed the etiology of myxœdema to be very obscure.

He dwelt at some length upon the pathology of the disease and its relation to the pathology of other puzzling reflex maladies. Post-mortem examinations have not been numerous, careful, or searching. No microscopical examinations have been made of the brain, medulla, cord, or sympathetic ganglia. However, it is generally conceded that the primary lesions are in the nervous system. The existence has been established of a principal vaso-motor centre in the medulla which, when irritated, contracts the vessels and lowers the general temperature. This centre Dittmar locates in the lateral columnar tract of the formatio reticularis, between the corpora quadrigemina and the calamus scriptorius. The experiments of Goltz and others show that this centre controls the action of the lower centre or centres. This centre is near the origin of the trigeminal, the hypoglossal, and the auditory nerves; disturbances of which will produce salivation, facial anæsthesia, an ataxic condition of the tongue, and impaired hearing. Irritation of certain parts of the floor of the fourth ventricle, near the above-mentioned vaso-motor centre, will produce glycosuria. Gruetzner found that an irritation of the medulla that would cause profuse salivation also caused irritation of the sympathetic, evidenced by general rather than local manifestations. Dr. Hamilton therefore believed that a tissue change, even that limited to the medulla, was capable of producing a general disorder of the trophic centres. He refers the seat of the primary lesion in myxœdema to the principal vaso-motor centre in the medulla. The mental symptoms are caused by the resulting vascular disturbances in the brain. The cutaneous trophic change he was inclined to refer to subsequent changes in the lateral and posterior columns of the cord. Cell degeneration in the giant cells of the anterior horns and the gray matter of the posterior columns has been observed in one case. Though the cause of the cutaneous change is obscure, there is significance in certain facts and experiments.

Raynaud and Arthaud have lately shown that in certain cases of spinal sclerosis, attended with trophic cutaneous derangements, there is degeneration of the spinal sympathetic ganglia, with disappearance of Remak's fibres and destruction of the nerve cells. Moreover there is a close connection between pigment alteration, thyroidal enlargement or atrophy, and mental disturbance. Myxœdema appears to be a sort of antithesis to exophthalmic goitre. In all carefully reported cases of myxœdema there are striking nutritive changes, indicative of a pathological upheaval of the sympathetic nervous system.

A microscopic examination of the skin showed great increase in fibrous tissue, and general evidence of a low inflammatory process. The vascular walls were thickened, and they were infiltrated with mucin. Though several sweat glands were seen, not one had a duct that was pervious to the surface. No nervous

degeneration was discovered. The brain shows atheromatous vessels, and is anæmic

The only affections from which it really needs to be differentiated are the various forms of renal disease. Myxœdema should include only cases with tough elastic swelling, mental derangement, speech defects, thyroidal atrophy, deafness and constant lowered temperature.

The prognosis is usually bad. It probably belongs to the long list of progressive degenerative and fatal disorders of the nervous system. Its course is a comparatively long one.

The treatment is not very satisfactory. Jaborandi has been tried without avail. Sulphur baths have been recommended. Nitrite of amyl, and nitro-glycerine in $\frac{1}{50}$ drop doses, have proven beneficial.

The paper closed with a bibliography of the subject.

DR. BALL, being called upon to introduce the discussion, remarked that he did not propose to discuss the paper. The only contribution he could make was to refer to two or three points of interest in a case of myxœdema now under his own observation. The patient was a woman forty-five years of age, whose myxœdemic symptoms dated back nine years. Her general health was in such a condition that in all probability she would live several years longer. Before she came under the Doctor's treatment, which was eight years ago, she was under the care of another physician, who was extremely puzzled in regard to her case and had made a diagnosis of idiopathic anæmia. When the patient first came under the observation of Dr. Ball, some eight years ago, the objective symptoms of the disease were quite characteristic. Her mental symptoms, though peculiar to the disease at that time, were not as marked as at the present. About a year after she began to manifest symptoms of the disease, her menstruation ceased entirely and remained absent five years, at the end of which time she became pregnant, and, arriving at full term, she was delivered of a healthy child, who still lives and is in good health. In 1877 the patient was seen by a prominent neurologist of this city and a diagnosis of Addison's disease was made, together with the prognosis of fatal result within a year. No very good reason for such a diagnosis was apparent, the only symptom which might lead to the suspicion of the disease being bronzing of the face.

There was one other point of some interest in the case to which he would like to refer, and that was that although the œdema in the majority of these cases is a solid œdema, yet there are cases, and the one under consideration is one of that kind, in which there is a certain amount of ordinary œdema; that is to say, the feet and ankles do pit on pressure as much as in the ordinary anasarca of Bright's disease, and this is independent of any trouble with the kidneys. Examinations of the urine in this case were begun as far back as nine years ago, and have been repeated at intervals up to the present time with the result of finding no evidence of renal disease. Hence it will be seen that the œdema is not always solid.

There is still a third point of interest in the case, namely, that the patient is subject to paroxysmal enlargement of her whole body. This enlargement of the body is so manifest as to attract the attention of her friends. It is marked by the diminution in the secretion of urine for three, four, or five days, at the end of which time she begins to pass large quantities of limpid urine, and the swelling of her body subsides so rapidly that she says she can almost feel herself becoming smaller. Dr. Ball was not aware of this being a common symptom of the disease, but in his patient it was well marked.

The hair of the head in this patient had fallen off to a considerable extent, and from the axillæ and pubes it had entirely disappeared. The typical facial expression of myxœdema is very marked in this case, so much so that when she was seen unprofessionally in this city by a physician, during the absence of the speaker, the physician was forcibly impressed by it, and though he had never seen a case of myxœdema, he wrote a letter to Dr. Ball on the following day asking if his patient was not suffering from myxœdema; so exactly did her facial expression resemble that described as peculiar to the disease. Dr. Ball thought these facts went to show that we had to deal with a special form of disease, and not a part of the general form of disease which Sir William Gull, Mahomed, and others have described. Dr. Mahomed had laid a great deal of stress upon the fact that Bright's disease is not confined to the kidneys, but is a general disease; that only 30 per cent. of the cases of Bright's disease die of the renal lesion. It was thought that to consider myxœdema as only one form of Bright's disease was rather stretching a point. The symptoms present were so entirely different from those of ordinary Bright's disease, or even the general form of Bright's disease to which authors have alluded, that it seemed proper that the disease should not be looked upon as a special one. The nervous symptoms were not the same as those found in Bright's disease and these were, not oftentimes, but generally, seen in the early stages of the disease. In his own patient the mental inactivity was a marked symptom early in the disease.

DR. BULKLEY said that he had had the pleasure of seeing five of Dr. Ord's cases presented at the International Congress in London, more than a year since. Some of the cases he thought would not have been recognized from their appearance as cases of myxœdema unless carefully examined. Two of the patients, however, were remarkably stupid. One or two had the drooping head characteristic of the disease. The affected tissues were enlarged by a process of non-inflammatory infiltration. An important point seemed to be the early recognition of the disease. The speaker had two patients now under observation in which he thought it was probable that myxœdema was present. In one the œdematous swelling was very marked upon the hand, and her facial expression was quite characteristic. She is a music teacher by occupation, and is a person who is constantly under enormous mental strain. Preceding the development of her present condition she had two attacks of an inflammatory condition of the skin with eczematous patches, and the formation of large boils. On these occasions she suffered greatly. The second patient was a very nervous lady, and had only come under observation within the past two or three days. He was unable to offer any suggestions regarding treatment. He referred to a case exhibited at the Dermatological Society in which myxœdema was suspected.

DR. ALEXANDER said that the patient referred to by Dr. Bulkley had suffered since two years of age from swelling of the face, which seemed to be a hypertrophy of tissue rather than a condition characteristic of myxœdema.

DR. W. T. ALLCHIN, of London, being called upon by the Chair, after characterizing the paper of the evening as, in his opinion, the most masterly summary of existing knowledge on the subject of myxœdema, said that he had no clinical experience with the disease. He thought that the point of special importance in connection with the disease just now was the consideration of its possible cause. The determination of the causes of disease was one of the most difficult parts of our knowledge, and it seemed that in this case the ordinary difficulties were added to on account of medical gentlemen being somewhat shy in expressing opinions fully, for fear of rashly anticipating views which

may soon be disproved. He thought that the expression of the opinion that the disease was of neurotic origin might be a source of fright to some. We were singularly deficient in our knowledge of the minute morbid anatomy of the disease, and he thought that the most important point of Dr. Hamilton's paper was, after all, the description of the microscopical appearance of the piece of skin removed from his patient. Pathologically, he thought, the lesion would be found to be a trophic change in the connective tissue. The presence of the nuclear overgrowth and mucin showed a failure in the reparative processes and consecutive growth of tissue. He thought we were hardly warranted in making conjectures as to whether the disease was of central or peripheral origin until we ascertained by post-mortem studies what tissues were principally affected.

There were no further remarks upon the paper.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 14, 1882.

T. M. Markoe, M.D., President, in the Chair.

Dr. E. L. Keyes read a paper on

PNEUMO-URIA.[1]

Dr. H. B. Sands thought that most surgeons had seen cases in which a gas had been expelled from the bladder; but, in the large majority, as had already been stated by Dr. Keyes, there existed a fistulous communication with the intestinal canal. There were some pathologists who believed this to be the only source of gas in the bladder, except when atmospheric air was introduced from without. One eminent medical authority, Dr. A. Clark, doubted the possibility of gas being the result of decomposition of the contents of the bladder. Dr. Sands had got so far, however, as to believe that such was sometimes the fact, and he could recall distinctly two cases, and indistinctly a third, in which he had concluded that the gas which was emitted from the urethra in considerable quantities, was the result of decomposition of blood-clots remaining in the bladder during severe hæmaturia. One of these patients he saw, many years ago, in consultation with Dr. McCready, and a careful examination failed to reveal any fistula. The air never escaped from the bladder except during attacks of hæmaturia, and not always then. He was not positive whether it was odorless. He believed careful and further inquiry was necessary in order to establish the fact that atmospheric air was ever found in the urinary bladder, unless it had been introduced from without. To the careless statement made by Mallez that, "it was not uncommon to find air in the bladder," he would not attach any importance whatever.

With regard to the probability of air being secreted by the vesical wall, he doubted whether there was any close analogy between the bladder and the intestines. He was not aware to what extent the gases of the intestine were the result of a secreting process on the part of its lining membrane, and how far they were the result of fermentative changes occurring in its contents. He believed, however, that the alimentary canal contained no atmospheric air beside that which had been swallowed in the ingesta. The organ analagous to the urinary bladder was the gall-bladder, and he was not aware that air had ever been found in that viscus.

The President asked whether or not it had been determined by physiologists or chemists that atmospheric air could be produced by decomposition of any kind. He thought he was quite safe in assuming that no form of decomposition gave rise as one of its products to atmospheric air, and, therefore, that if the gas in the bladder in the cases reported had been proved to be atmospheric air, the probabilities were in favor of its having come from without.

Dr. L. A. Stimson, referring to the case mentioned by Dr. Keyes in which the gas was proved to be nitrogen, said that free nitrogen was not a product of the putrefaction of an albuminous substance like blood. Free nitrogen in very small quantity was held in solution in the blood, but so also was oxygen; and there was no reason to suppose that either would be given up by the blood to remain free in the bladder. A possible source of the nitrogen was the urea of the urine in the bladder. A common method of quantitative analysis of the urea is to decompose it, and measure the volume of its nitrogen, and as a small amount of urea furnishes a large bulk of nitrogen (one grain gives nearly two cubic inches) a very extensive decomposition would not be needed to produce the amount of gas observed. The decomposition is effected by very simple measures, the addition of Labarraque's solution, outside the body, and it might perhaps be as readily effected within it.

Dr. Weir referred to two cases in which, the patients suffering from cystitis from an enlarged prostate, air was discharged from the bladder through the urethra, but probably it was admitted from without, as a catheter was in frequent use in both cases. He would add to the references made by Dr. Keyes, an excellent article written by Blanquinquic on vesico-intestinal fistulæ, in which the writer speaks of air being found in the urinary bladder, but does not consider it to be clearly established, and he gives his conclusion that the spontaneous discharge of bubbles of air at the close of urination indicates without doubt that the cause of these is the intestine.

Dr. Keyes was quite certain that he had seen a case in which gas was formed in the stomach of a patient who had diabetes, and finally died of albuminuria. He took no food whatever by the mouth during a long period, and yet he belched enormous quantities of gas.

He had also seen one case where gas appeared in the bladder, as the clot from hæmaturia was breaking up, and he supposed it arose from decomposition of the blood.

Dr. George A. Peters recalled a case in which there was considerable gas in the bladder in connection with hæmaturia, and it ceased when the hemorrhage stopped. He supposed that the gas was one of the results of decomposition of the clot.

NEWS ITEMS.

HERKIMER, N. Y.

(*From our Special Correspondent.*)

The Herkimer County, N. Y., Medical Society and the New York Code.—At the semi-annual meeting of the Herkimer County Medical Society, held December 5, the following preambles and resolutions were passed, only one vote having been recorded against the motion:

Whereas, The New York State Medical Society, at its last annual meeting, adopted a new system of ethics, in place of the code hitherto in force, for the guidance and conduct in practice of the medical profession of this State, and,

Whereas, We believe that in making the radical changes therein contained they have placed us directly in conflict with the parent organization, the American Medical Association; therefore,

Resolved, That we, the Herkimer County Medical Society, hereby declare our continued allegiance to the precepts and ethical Code of the American Medical Association, adopted June 15, 1847.

Resolved, That the delegate to the State Medical Society be instructed to urge by all honorable means the repeal of the existing Code.

Thirty-four of the New York County Societies have already declared against the new Code, and but two have accepted it.

BROOKLYN.

(*From our Special Correspondent.*)

THE SUIT FOR MALPRACTICE AGAINST THE LONG ISLAND COLLEGE HOSPITAL.—The recent suit of Carl Eibee against the Long Island College Hospital to recover twenty-five thousand dollars on the ground of alleged malpractice by the surgeons of that hospital, while he was an inmate under treatment for severe injuries caused by the fall of a boiler upon him, was dismissed by Justice Gilbert, in the King's County Supreme Court, the Court holding that neither malpractice nor negligence were shown. This case was watched with much interest by the neighboring profession.

BALTIMORE.

(*From our Special Correspondent.*)

THE INFLUENCE OF DIGITALINE UPON THE HEART.—MESSRS. H. H. DONALDSON, A.B., Fellow in Johns Hopkins University, and L. T. STEVENS, A.B., have been conducting a series of observations upon the influence of digitaline upon the heart of the slider terrapin and the frog. Their very interesting results are appended, and it is to be hoped that they will be asked to continue their researches upon the isolated mammalian heart, as proposed.

The results which we have to mention are derived from two groups of experiments. The first was carried on by Messrs. Warfield and Donaldson during the first five months of this year; the second, which is simply a continuation of the first, has been carried on by Messrs. Donaldson and Stevens since October. Though they are not yet complete, we are, however, able to give some of the results which have been obtained.

The first investigation was on the work of the heart, and the object was to determine whether the work done by the isolated heart was increased or decreased by moderate doses of digitaline. The heart of the slider terrapin was used (*Pseudemys rugosa*, Shaw). Carefully isolating the heart from its connection with extrinsic nerves and the rest of the circulatory system, it was supplied with a continuous stream of blood under conditions of pressure and temperature as near the normal as possible. It was then found that when the heart, beating normally, was treated with a small dose of digitaline, the work invariably decreased. The full account of these experiments was published in the *Studies from the Biological Laboratory of Johns Hopkins University*, vol. ii., No. 3. This fall, the frog (*Rana mugiens*) was used instead of terrapin; the same result, however, followed—*i. e.*, the work done by the heart decreased under moderate doses of digitaline.

With a view to testing the influence of abnormal blood pressures on these results, some experiments were made in which both venous and arterial pressures were varied within wide limits, but the work always decreased. To test the effect of aortic insufficiency, the canula was pushed in the aorta down past the semilunar valves into the ventricle itself. Under these conditions the heart weakened very fast, but the only effect of digitaline was to decrease the work. A study of the separate beats of the frog's heart shows that the work at first decreases, because the excursion of the ventricle—the variation of capacity between diastole and systole—is somewhat decreased, the rate of the pulse being only slightly diminished. Later the pulse is often slowed to half the normal rate while the work has by no means decreased proportionally, This arises from the fact that the excursion of the ventricle is now much greater than is normal, and thus somewhat compensates for the diminished pulse rate. In this latter case the individual beats of the heart are very much strengthened.

To test the variation in form which takes place in the heart under digitaline, use was made of Roy's tonometer (*Journ. of Physiology*, vol. i., No. 6). By this means one can determine whether the primary diminution in the excursion of the ventricle is due to a gradual shrinkage or distention of the ventricular muscle. Experimenting with the isolated ventricle, they have always obtained evidence of a shrinkage—that is, the ventricle tends more and more to remain in the systolic condition. They have not yet been able to observe in these experiments the condition of the ventricle described above, where it beats slowly, but at the same time with an excursion much greater than normal.

The isolated auricles also shrink under the action of digitaline. This shrinking of the auricles can be directly observed in the heart of the terrapin without the aid of any apparatus, but in the case of the frog it requires the tonometer to make it plain. The variations in the volume of the whole heart have not yet been tried.

By moderate does are meant, from .0005–.002 grm. of the soluble German digitaline mixed with 100 cc. of nutrient fluid. The drug used was prepared by Merck.

The bearing of these results can be briefly noted. Starting from the fact that they do get a rise of blood pressure under digitaline, it is evident that this rise is not due to the heart, because, under all varieties of conditions, the heart does less work.

The rise must then be due to a narrowing of the arterioles, a view maintained by many, but on which they can, as yet, offer no direct evidence. It appears, then, that digitaline is a drug by means of which we can maintain a high arterial pressure and at the same time reduce the amount of work done by the heart itself.

It is hoped in the course of the year to extend these observations to the isolated mammalian heart, and thus render the series of experiments complete.

NEW ORLEANS.

(*From our Special Correspondent.*)

YELLOW FEVER.—Among the recent admissions to the Charity Hospital, was one of yellow fever: At least such would be the almost unanimous verdict of our profession throughout Christendom, if the symptoms and facts were laid before them.

The facts as presented are as follows: An English seaman arrived at New Orleans on the 15th of November, his ship having touched at several ports in the island of Cuba, but certainly at Cienfuegos on Sunday, November 12th. The ship left Cienfuegos on the 13th, on which day the sailor took sick. He was brought to Charity Hospital on the day of arrival. "On the 17th at 8 A.M., temperature, 100°; pulse, 60; vomiting fluid with dark deposit; eyes injected and jaundiced; body slightly jaundiced; dark brown coating over tongue—edges and tip very red; gums much congested, and bleeding on slight pressure; has passed no urine for fifteen hours; catheter introduced and two ounces drawn—nearly one-half albumen. He complained of thirst and pain in the epigastrium. At 7 P.M., temperature

100°.5; pulse 72, weak; restless; mind clear; eyes and surface more jaundiced; vomited a basin half-full of dark grumous fluid; one and a half ounces of urine obtained by catheter, one-third albumen. 10 P.M., very restless, delirous; pulse barely perceptible; convulsions and death at 10.30 P.M." During his sickness well-marked extravasations occurred around mosquito-bites upon his face and hands.

In this case the death was entered upon the mortality records as having been caused by "hemorrhagic malarial fever."

In all instances where it is possible to do so, the facts connected with these fatal cases of "hemorrhagic malarial fever" should be laid before the profession for instruction and such criticism as may appear to be proper. Otherwise we are liable to the charge of employing the term as a scapegoat for either erroneous diagnosis or for premeditated concealment of the true nature of the disease.

We have seen some hundred or more cases like the one just reported, but among the whole number not one could be properly referred to the swamp-poison. There is no point more strongly marked in the whole range of medical pathology than the contrast between the malarial poison and the yellow fever poison in establishing a hemorrhagic diathesis.

People may preach heresies in religion or in astronomy, and declare that the "sun do move," and we may be speedily rectified without appreciable damage. But the inexperienced observer, after reaching such a clinical report of symptoms and the diagnosis, may innocently enough allow a real case of yellow fever to breed a destructive epidemic.

THE ANNUAL DINNER OF THE MEDICAL AND SURGICAL ASSOCIATION has just been celebrated. The occasion was unusually agreeable.

THE NEW ORLEANS MEDICAL AND SURGICAL JOURNAL has just been purchased by Dr. W. H. Watkins. Dr. S. M. Bemiss, the senior editor of this periodical, has retired from medical journalism. The new editorial corps will appear on the cover of the December number of the Journal. Your correspondent does not know how the names will be arranged, but he does know that men of ability will be joined with the new editor, and that the Journal will gain in interest and value by the change.

CANADA.

(*From our Special Correspondent.*)

ONTARIO HEALTH BULLETIN.—The Provincial Board of Health of Ontario is publishing a weekly bulletin, in form of a colored map, on which the Province is divided into ten districts, and the six diseases most prevalent in these are arranged in order of their prevalence; at the same time the percentage of each disease is given. From the map we gather that malaria prevails extensively in the three districts bordering on Lake Erie. In No. 10, the Lake St. Clair district, the percentage of intermittent fever is given as 22. In district No. 3, the Muskoka region, 8 per cent. of the cases reported were gonorrhœa. The word "Lumbermen," printed across this region probably explains the fact. A weather report accompanies the map, and diagrams showing the comparative area of prevalence of the various diseases.

The publication of the bulletin will do much towards directing the attention of the profession and public to sanitary science.

PUBLIC HEALTH.—The most important health convention which has taken place in the Dominion met in Ottawa on the 6th and 7th of this month. Delegates were present from each of the Provinces, and the whole question of vital statistics thoroughly discussed. The following resolutions were carried:

1. That a uniform system of collecting and compiling health statistics be adopted for the whole Dominion.

2. That the Dominion Government be requested to take measures to procure reliable health statistics from every city, town, or municipality where local boards of health are now or may hereafter be established, with the view of determining the locality and nature of diseases to which Canada is subject.

3. That a Bureau of Vital Statistics be established at Ottawa in connection with one of the public departments.

The delegations afterwards met the members of Government and presented a series of resolutions. Unfortunately, the Act of Confederation leaves health matters with the local government, while the Dominion Government has to do only with vital statistics. The possibility of amending the Act was discussed. A meeting was subsequently held, and the necessary preliminary steps taken to organize a Canadian Sanitary Society.

VIENNA.

(*From our Special Correspondent.*)

PRIORITY CLAIM FOR INTRODUCTION OF IODOFORM.—At a recent meeting of the Society of Physicians in Vienna, Prof. E. Ludwig read a very valuable paper upon iodoform. In the discussion which followed, a very spirited dispute arose as to the priority claim of introduction of the remedy into surgery.

Dr. Braum, Prof. Mosetig's assistant, claimed the honor for his *Chef.*

Docent Dr. Kohn affirmed that Lazauski, in Prof. Pick's clinic, applied the remedy before any one else, in the treatment of venereal ulcers.

Docent Dr. Grünfeld asserted that he, himself, had used an iodoform salve still earlier.

Prof. Ludwig quietly put an end to the angry disputation by saying that the literature of the subject showed very plainly that the drug had been extensively used, in very various diseases, as early as 1822.

DR. MORRISON, OF BALTIMORE.—Dr. Morrison, of Baltimore, who has been studying dermatology and syphilis for a long time in Vienna, with Profs. Neumann and Kaposi, is announced for a paper before the next meeting of the Society of Physicians of Vienna, embodying his recent researches upon the bacteria of syphilis.

A NEW INSANE ASYLUM FOR EASTERN NEW YORK.—A resolution was introduced at the meeting of the Board of Supervisors held at Poughkeepsie, last Monday, urging the erection of another Hudson River State Hospital for chronic insane cases, for the accommodation of the eastern portion of the State, and asking the co-operation of the Supervisors of the counties of Clinton, Franklin, Warren, Washington, Saratoga, Rockland, Albany, Rensselaer, Green, Columbia, Westchester, New York, Kings, Queen, and Suffolk.

DR. HOLMES' SUCCESSOR.—DR. THOMAS DWIGHT, former professor of anatomy at Bowdoin College, and grandson of Dr. John C. Warren, the predecessor of Dr. Holmes, will complete the course of lectures on anatomy at the Harvard Medical School this winter.

SURGEON-GENERAL OF NEW YORK.—Governor-elect Cleveland, of New York, has just appointed Joseph D. Bryant, M.D., professor of anatomy in Bellevue Hospital Medical College, Surgeon-General of New York State.

The Library of the Surgeon-General's Office.—The Medical Society of King's County has adopted the following resolution in support of the present management of the Surgeon-General's Library.

Resolved, That the Medical Society of the County of Kings learns with regret that there is danger that the Surgeon-General's Library, which is considered the most complete medical library in the world, will be merged into the Congressional Library; and hereby urgently but respectfully requests that the Representatives in the Senate and Congress from this State will oppose any change in the present administration of the Surgeon-General's Library, and that they will use every justifiable means to preserve and protect that library under the same direction that has made it so peculiarly valuable and instructive to the entire medical profession of the United States.

Prof. W. H. Flower, F.R.S., has been awarded one of the royal medals of the Royal Society, of the value of fifty guineas, for his contributions to the morphology and classification of the mammalia, and to anthropology.

Guiteau's Brain.—Dr. E. C. Spitzka, at a late meeting of the New York Neurological Society, of which he is President, stated that the specimens of Guiteau's brain which he had examined showed all the signs of disease described in the official report published in The Medical News. "He intimated that Dr. Dana's report in the *Medical Record* was 'fixed' to make it correspond with the editorial views expressed in that journal."

Gift to the Pacific Medical School.—The dedicatory exercises of the new Cooper Medical College building were held in San Francisco on November 4th. The building was erected at a cost of one hundred thousand dollars, at the expense of Dr. L. C. Lane, and by him dedicated to the memory of his uncle, the late Dr. Elias Samuel Cooper, one of the early pioneers of California. The Pacific Medical College, which is reincorporated under the title of the Cooper Medical Faculty, retains its faculty unchanged.

Prosecution of Illegal Practitioners.—For practising medicine without complying with the laws of the State, several persons were arraigned in the New York city Police Court, last week, on complaint of Dr. David Webster, President of the County Medical Society. Eliso F. Marini, of No. 143 Prince Street, had no diploma. He was convicted of the same offence in Special Sessions on October 27th, and fined $50. He was held on the present charge in $500 bail. John F. A. Clausnitzer was accused of practising under the name of John C. Adams, at No. 29 Bleecker Street. He had a German diploma. He said that he could not afford to purchase a new sign, and so allowed the sign of Dr. Adams, who formerly occupied the premises, to remain where he found it. He was held in $300 bail, and at once deposited the money. George H. Schwab, of No. 59 Bond Street, had no diploma. He was held in $300. William H. Fuller, of No. 24 Varick Street, had a bogus diploma issued in Philadelphia, and was in consequence held in $300 bail. Francis E. Ruhenberg, a Swede, of No. 80 Christopher Street, advertised irregularly to cure diseases of the limbs. He was held in $300 bail.

Penalties for "Skin" Plumbing.—Dr. Henry D. Nicoll, of No. 7 West Thirty-ninth Street, New York, deserves the thanks of the community for his energy and courage in bringing to justice James McLoughlin, a plumber of No. 157 West Forty-first Street. Dr. Nicoll recently brought suit against McLoughlin in the Court of Common Pleas to recover damages for the "fraud and deceit" of the latter. It appeared upon the trial, from the testimony of Dr. Nicoll, Gen. F. T. Locke, and other reputable witnesses that Dr. Nicoll, in 1878, requested McLoughlin to examine the plumbing in his house and to report what alterations and repairs were necessary to put it in perfect condition. McLoughlin gave his estimate in writing with some detail, and the doctor instructed him to proceed according to the estimate.

In due time the plumber reported that every detail had been complied with, and his bill was paid in full.

Subsequently, from time to time, the doctor detected unpleasant odors pervading his house, which he attributed to sewer gas, and he called upon McLoughlin to put a fresh air inlet inside the main trap on the main drain. McLoughlin made objections, and thereupon the doctor called upon Messrs. Locke & Munroe to make an examination of the plumbing, and their workmen uncovered work which would seem fully to sustain the charge of "fraud and deceit." The house drain, which was of cast iron, and buried in the ground, had few joints caulked; the lengths of pipe were so laid that some pitched towards the house and some towards the sewer; it was impossible for water to run fully out of the drain, except at the open joints into the ground; two lengths of pipe were used which had holes drilled into them, and the refrigerator waste was simply dropped into a hole drilled into the drain pipe; in one place, two spiggot ends were simply laid together, surrounded by a piece of larger pipe, into the intervening space of which some cement had been thrown; and finally, no main trap was placed on the main drain, although the defendant had repeatedly informed the plaintiff that one was there.

The jury promptly rendered a verdict in favor of the doctor for $125.

Dr. Nicoll has rendered a valuable service, not only to the householders, but to honest plumbers by making an example of this man and establishing a healthy precedent. If this were more frequently done by persons who suffer by dishonest work of plumbers, there would be less bad work done and fewer occasions to inveigh against the craft.

We have noticed this case at length, in accordance with our policy to expose dangerous work whenever brought to our attention.—*Sanitary Engineer*, November 16, 1882.

Amsterdam Exhibition, 1883. — The Executive Committee of the International, Colonial, and Export Trade Exhibition to be held at Amsterdam, May to October, 1883, has resolved, at the suggestion of the Dutch Association for the Advancement of Medical Science, to add a section for colonial medicine, to be opened simultaneously with the colonial exhibition. The aim of this section will be to promote a knowledge of the sanitary and medical conditions in the colonies. The programme of the section divides its exhibit into three classes. The first class will embrace everything relating to the ministration of public health, such as water supplies, adulteration of food, intoxicating drinks, schools, prisons, cemeteries, sewers, cesspools, trades detrimental to health, measures against endemic, epidemic, and contagious diseases, prostitution, vaccination, vital statistics, etc. The second class will be devoted to data connected with the organization of the medical science in the colonies, in regard to which the several colonial governments follow different systems, and it is only by a careful comparative study of them that a correct judgment can be formed as to the best system to be adopted. The third class will have for its scope the attendance to and transport of the sick and

wounded, and will include models, plans, and drawings of hospitals, lunatic asylums, leprosies, etc., means of transport by land and water, medical literature, and native drugs. Objects of a commercial or not strictly scientific character will not be admitted into the section.

SMALLPOX IN SOUTH AMERICA.—This disease is prevailing in many parts of the country. It has been spreading among the population of Rio de Janeiro for many weeks back, but the health authorities have only recently declared the disease epidemic, and adopted active measures to restrain it. Vaccination has been made compulsory, but there is much difficulty experienced in obtaining good vaccine virus. The reports show 67 deaths from smallpox in the city during the week ending October 28th. At Desterro, St. Catharina Island, the disease is disappearing having apparently exhausted all the susceptible material. During the past nine months in this small municipality, having a population of about 8000, there have been 141 deaths from smallpox. About 10 per cent. of the cases were fatal. At Blumenan, a small German colony in St. Catharina province, of 27 persons who were seized with the disease, only 4 survived the attack.

CONTAGIOUS DISEASES IN NEW YORK CITY.—Dr. Janes, Assistant Sanitary Superintendent, has prepared the following table of contagious diseases reported at the Sanitary Bureau in the last three months, compared with the reports for the same months in 1881:

1881.	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningts.	Measles.	Diphtheria.	Smallpox.
September	2	132	270	26	37	302	48
October	0	138	425	17	48	390	53
November	27	129	607	18	183	398	74
Total	29	399	1,302	61	268	1,090	175
1882.							
September	1	117	88	20	21	116	2
October	0	147	110	12	40	153	3
November	0	68	124	12	60	185	3
Total	1	332	321	44	121	454	8

DIPHTHERIA IN PHILADELPHIA.—There has been no appreciable change in the mortality from diphtheria in Philadelphia during the week ending December 9th. The mortality is still excessive. The number of deaths for the week was 41, or one less than the number reported in the week preceding.

Deaths were reported in 19 out of 31 wards; and in 7 of these no deaths had been reported in the previous week. On the other hand, we find that in 8 wards reporting deaths from this cause in the week ending December 2d, not a death is reported for the week ending December 9th. These facts seem to indicate that strictly local influences are not the chief factors concerned in the propagation of the disease.

There were only 3 deaths in Frankford (where the disease has been most prevalent), against 7 in the preceding week; 5 in the 24th Ward, the same as last week; 4 in the 25th Ward, against 2 last week; 4 in the 16th Ward, where there were none last week; and 3 in the 15th Ward, where there were also none last week.

Nearly all the deaths were of children under 10 yeas of age. Under 10 years there were 37 deaths; between 10 and 15 years, 2 deaths; between 20 and 30, 1 death; and between 30 and 40, 1 death.

Cases of the disease are reported in 28 wards, the total number being 155, or 10 less than last week. The 3d, 5th, and 9th Wards reported no cases during the week. The greatest number of cases were reported in the 1st, 19th, 23d, 25th, 27th, and 29th Wards.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending December 2, 1882, indicate that neuralgia has greatly increased, that cholera morbus has considerably increased, that diphtheria, erysipelas, and whooping-cough have increased, that intermittent fever has greatly decreased, and that typho-malarial fever has considerably decreased in area of prevalence.

Compared with the average for the month of November in the preceding five years, neuralgia and diarrhœa were more prevalent, and intermittent fever, pneumonia, whooping-cough, consumption, and diphtheria less prevalent during the month of November, 1882.

For the month of November, 1882, compared with the average of corresponding months in the preceding three years, the temperature was higher, the absolute and relative humidity more, and the day and night ozone less.

Including reports by regular observers and by others, diphtheria was reported present during the week ending December 2 and since, at twenty-six places, scarlet fever at fourteen places, and measles at five places. Smallpox was reported at Lyons, Ionia Co., December 1.

Sanitary inspectors report two cases of measles found among immigrants arriving at Detroit, during the week ending December 2.

OBITUARY NOTICE.—DIED on November 17th, PROF. GEORGE GULLIVER, F.R.S., F.R.C.S. Prof. Gulliver was born on the 4th of June, 1804, and received his medical education at St. Bartholomew's Hospital. In 1861 he was elected Hunterian professor of anatomy and physiology, and is best known by his researches on the chyle, blood, and lymph.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 4 TO DECEMBER 11, 1882.

MOORE, JOHN, *Major and Surgeon.*—The extension of leave of absence granted Nov. 3, 1882, is still further extended one month.—*Par. 4, S. O. 283, A.G.O.*, December 6, 1882.

CRAMPTON, LOUIS W., *Captain and Assistant Surgeon.*—Granted four months leave of absence.—*S. O., 280, A. O., G. December 2*, 1882.

GOMGAS, W. C., *Assistant Surgeon.*—Relieved from duty at Fort Brown, Texas, and will accompany the 19th Infantry to Forts Clark and Duncan, Texas. Their future stations will be announced.—*S.O. 130, Department of Texas, November 27*, 1882.

MADDOX, T. F. C., *Assistant Surgeon.*—Relieved from duty at Fort Brown, Texas, and will accompany the 19th Infantry to Forts Clark and Duncan, Texas. Their future stations will be announced.—*S. O. 130, Department of Texas, November 27*, 1882.

REED, WALTER, *Captain and Assistant Surgeon.*—Assigned to duty as attending surgeon headquarters Department of the Platte.—*Par. 2, S.O. 127, Department of the Platte, December 4*, 1882.

TAYLOR, MARCUS E., *Captain and Assistant Surgeon.*—The leave of absence granted Aug. 14, 1882, is extended two months.—*Par. 6, S.O. 283, A.G O., December 6*, 1882.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLI. SATURDAY, DECEMBER 23, 1882. NO. 26.

ORIGINAL LECTURES.

DIPHTHERIA AND ITS TREATMENT,

BASED ON RECENT INVESTIGATIONS.

A clinical lecture delivered at the Philadelphia Hospital, December 6, 1882,

BY J. M. KEATING, M.D.,

ONE OF THE ATTENDING OBSTETRICIANS TO THE PHILADELPHIA HOSPITAL, AND LECTURER ON THE DISEASES OF WOMEN AND CHILDREN, ETC.

(Reported by WILLIAM H. MORRISON, M.D.)

AT the last lecture, as you may remember, I spoke of some of the acute varieties of diseases of the throat in children. I propose to-day to make some remarks in reference to the clinical aspect of the subject of diphtheria, based upon the experiments upon animals and observations in the practice of some of us who are interested in this subject at the present time. At my last lecture, I pointed out to you the differential diagnosis of the various forms of acute laryngeal disease in children; these were spasmodic laryngitis, or false croup, one of the most important and most frequent of these diseases; a combination, as it were, of simple acute laryngitis, and laryngismus stridulus, and pseudo-membranous laryngitis, or true croup. I showed you at that time how pseudo-membranous laryngitis differed in its symptoms from spasmodic laryngitis, especially in this fact, that in the former there was present a false membrane, which, by causing mechanical obstruction and interfering with respiration, gives rise to other symptoms not found in the latter disease. At the present time the most important subject which can come before us is the difference, if there be any, between pseudo-membranous laryngitis and the disease known as diphtheria, which is also characterized by a membranous deposit upon the mucous membrane of the throat, fauces, and nares, sometimes extending into the larynx and trachea, giving rise to various symptoms, many of which are due to the presence of membrane obstructing the tracheal opening. I believe that the former affection is always associated with the laryngeal and tracheal forms of the latter, usually presenting its most marked symptom, but that it can occur by itself as the result of cold or irritation as well as its analogue croupous pneumonia. I told you that the mucous membrane of the pharynx differs anatomically from that of the larynx and trachea, and that, therefore, irritation and inflammation of these two parts give rise to entirely different sets of symptoms. The mucous membrane of the pharynx is covered by a thick, almost impenetrable layer of squamous epithelium. This is placed on a loosely attached submucous tissue which is capable of being greatly distended by infiltration and by blood, so that inflammation of this membrane will cause congestion and œdema to take place below the epithelium, and may give rise, at the same time, to the appearance of but slight congestion of its surface when the disturbance beneath is very great. The mucous membrane of the larynx and trachea is covered by the ciliated form of columnar epithelium. This epithelium is placed upon a very dense basement membrane, and has behind it thick inelastic cartilage. Inflammation at this point will be rapidly followed by the appearance of fibroplastic lymph upon the surface, lifting the easily detached epithelium, and giving rise to layers of membrane; these deposits may form rapidly, and quickly occlude the larynx or trachea.

About the year 1868, Oertel found in the blood of persons suffering from diphtheria, a form of micrococcus, a peculiar granular matter. A full account of this subject will be found in Ziemssen's *Encyclopedia*, and in the supplement of the report of the National Board of Health for last year, but as this latter is not accessible to many of you, I go into this subject somewhat in detail. Many observers subsequently found that this peculiar matter, which occasionally took the form of little black granules, and again appeared in masses, was present in all cases of diphtheria, and in proportion to the severity of the attack. The presence of these micrococci has been positively substantiated, not only in diphtheria, but also in almost all of the so-called zymotic affections.

Those of you who attended the lectures in this hospital last spring, will remember the severe epidemic of measles in the children's ward at that time. The children died very rapidly, and it was impossible at first to account for their rapid death. Dr. Formad and myself made a number of observations on the blood of these cases, and it was found that as soon as the malignant symptoms presented themselves, the blood of these children was filled with micrococci. There were immense numbers of these; not only did they float in the liquid in masses, looking like frog-spawn on a pond, but they also penetrated the white corpuscles, and increased in numbers to such an extent as to cause the globule to burst in many cases, although the red corpuscles were not attacked. The severity of the symptoms was found to be in proportion to the number of the micrococci. Whether this was due to the micrococci, or whether the severity of the symptoms and the presence of the micrococci were simply coincident, I am not prepared to positively assert; we do know, however, that where this material was found in the blood, those children were in danger of death from the malignancy of the disease and from exhaustion, and also from heart clot. It has been found by many observers that these micrococci exist not only in the part where they are introduced, as in the blood of the throat in diphtheria, but they are also carried to the finest capillaries in the body, multiplying with great rapidity. They have been found in the marrow of the bones, and in the minute vessels of the kidney, clogging them, causing mechanical congestion, and finally either causing or attending a distinct diphtheritic process in the kidney analogous to that going on at the point of invasion. We observed in this epidemic of measles that the children would often exhibit extraordinary symptoms connected with the respiration. A child would be doing well, when suddenly it would seem to have difficulty in breathing. There would probably be, as is usual in such cases, a certain amount of pulmonary congestion and some catarrhal pneumonia, but at the same time the severity of the pulmonary lesions would not be in proportion to the disturbance of respiration which was present. The gasping spells were shown to be due to the fact that insufficient blood passed through the lungs to be oxygenated. There was no trouble about getting air into the lungs, but the trouble was to get venous blood from the right ventricle to travel into the lung. There was some obstruction. After death it was found to be due

to a white clot which had evidently formed some time before, and on microscopical examination this clot would be found to be filled with micrococci.

This is an extremely interesting subject, and those who have studied these conditions under the microscope have found that it was not only an interesting subject in itself, but one of great practical importance. I wish, to-day, in view of the present epidemic, to speak to you of some of the practical points which this matter brings before us. It is also of great importance in connection with treatment. From the experiments of Doctors Wood and Formad—experiments which have been verified and which are still going on—it has been proven that the initial lesion in cases of diphtheria is in the throat. It has for many years been a question whether diphtheria was like typhoid fever, scarlet fever, and other affections where the blood was first affected by the poison of the disease and a period of incubation resulted, and that this was finally followed by the peculiar characteristics of the disease, that is to say, the appearance of membrane in the throat in diphtheria, the scarlatinous rash in scarlet fever, and of rose-colored spots and so on in typhoid fever. These experiments have, I think, conclusively shown that diphtheria is a contagious disease, contagious from the membrane which is present, and that this contagious principle can be inoculated, can be transmitted directly to the individual, and also that it first appears upon that part where the inoculation has been performed independent of any lengthy period of incubation. If the membrane from a case of diphtheria is inoculated upon any part, it is at this point where the first manifestations will occur, while the constitutional disturbance will be of a secondary character. In all cases of diphtheria examination of the blood under the microscope shows the presence of these micrococci, and also that they first appear at the point of greatest intensity, or otherwise invasion, and thence make their way through the circulation to other parts of the body. In the primary stage they are found in the membrane, and in the epithelium on the surface of the tongue, mouth, and throat, and from these parts they rapidly penetrate into the submucous tissue, and finally are taken up by the bloodvessels and lymphatics, and develop with great intensity. These experimenters have declared that their observations have shown that diphtheria need not be a so-called specific affection; that in rabbits any inflammation of the mucous membrane of the throat may produce symptoms analogous to those of diphtheria with the presence of micrococci; they, at the same time, tell us that these micrococci are always found to a greater or less extent upon the mucous membrane of the throat and epithelial débris on the tongue of those in health, but not necessarily in the air which we breathe, unless it be foul. I can scarcely see my way clear to go as far as this, but believe that in a dormant state they may have their peculiar home in the epithelial detritus which is found in the mouth, and are deposited there and vivified by foul air from cesspool gases, and then if any irritation or denudation of the mucous membrane takes place from cold, from sore throat of any kind, especially in children, in whom there is a special vulnerability, these micrococci suddenly develop with great intensity and rapidly produce the malignancy which we see in the secondary manifestations of the diseases; their habitat being foul air, whence they are derived.

Let me here refer to the great error that is frequently made of calling one disease after another, *e. g.*, calling a sore throat *diphtheritic* because it has a membrane upon it, or a disease *typhoid* because it resembles typhus, or a rash *scarlatinous* because it resembles that of scarlet fever. The result of this is that people who do not know what these terms mean imagine that they have these various diseases, and you will be often told that a person has diphtheria every fall, because some one has called it a diphtheritic sore throat, or that a child has had scarlet fever a dozen times, when in reality it has suffered from attacks of erythema, or a person has been *threatened* with a disease of this sort! This use of terms is objectionable to those who are trying to attain a scientific accuracy in regard to the diagnosis and treatment of these diseases, and raises doubts in the popular mind.

Diphtheria, though possibly a disease which may occur more than once, carries with it a certain individuality of its own. The poison, whether it be micrococci or not, requires something which will increase its activity, and will, under ordinary circumstances, lie dormant. It may remain for some time in a pure atmosphere, and not develop the disease; but if it is exposed to sewer gas or to bad ventilation, this growth, this cause of diphtheria, is vivified, producing usually the primary affection of the throat, and eventually involving the general system; or the contagion may be direct from one individual to another. Experiments have proved this, in the fact that the most virulent of micrococci, that of erysipelas, if exposed to air which is pure, or, in other words, to oxygen, loses its intensity, and when inoculated shows its enfeebled powers.

Is this disease identical with true croup or pseudo-membranous laryngitis? In certain cases it may be. Oertel, in Ziemssen's *Encyclopedia*, describes two forms of the disease—the catarrhal and the croupous. The first is the result of catarrhal inflammation, which he supposes to be due to the action of a small amount of poison on the throat membrane, giving rise to a mild form of catarrh. This catarrh may come from any irritation. It is no more due to the specific action of diphtheria poison than it is due to the inhalation of fumes of nitric acid or of any other irritating substance. It is simply a superficial catarrh similar to a catarrh in the head. Thus, if you inhale the dust of ipecac, you will set up as severe a catarrh as if you go out into the night air without your hat. Then again, we have that which is described as the croupous form, which may also be dependent upon a specific blood poison, and has attending it a fibrinous exudation, with rapid failure of the system following the introduction of the poison, producing adynamia. We know that ordinary causes, presumably not dependent on diphtheritic poison, may produce laryngitis with the deposit of membrane. Children with this disease present certain appearances and symptoms which are not like those that are seen in the early stages of diphtheria. Those of you who have seen the two affections side by side will, I think, agree with me in saying that they are not identical in appearance. In a case of pseudo-membranous laryngitis, the child may have deposits in the trachea which may so obstruct the tracheal opening as to cause great interference with respiration, yet until the fatal signs come on, the symptoms are not identical with those of diphtheria; there is not that profound prostration, that swelling about the neck and angle of the jaw which shows great involvement of the lymphatics, with enlargement of the glands. In the former disease, the lymphatics are not at all affected in the early stage; and, again, when I tell you that more or less membranous deposit may be readily caused by the least irritation, you can easily see that it is not necessary to always account for its presence by a violent poison acting upon its surface. In the most severe forms of diphtheria the disease, originating in the pharynx, has a tendency to extend into the nasal cavity. In some cases, in adults, the larynx escapes almost entirely, or again the primary lesion may be in the trachea. Diphtheria is not limited to young children, but is quite common between the ages of 10 and

age of 15 years, and is as fatal at these ages as it is at the same number of months. Pseudo-membranous laryngitis, on the other hand, is quite rare after the age of five years.

It was not my intention to-day to point out these differences. There are some authorities who believe that the two diseases are identical, while others take the opposite view. For my own part, I take a middle course. I think that diphtheria may cause croup, as may any other irritant; they may both be present in the same case, and probably are in children, and one may be the exciting cause of the other. There is in children a tendency for all catarrhal conditions of the mucous membrane of the air-passages to exist, and I think we may look upon pseudo-membranous laryngitis as a constant symptom of diphtheria at this age; still, we know that diphtheria can occur in adults without pseudo-membranous laryngitis being present, and that the latter can take place in children with abundant deposits, but unaccompanied by lymphatic involvement and adynamia, unless septicæmia should set in from putridity of the false membrane.

My purpose to-day is to make some remarks in connection with treatment. In treating those cases of measles to which I have alluded, we used large doses of alcohol, in the form of whiskey, and we found that it diminished the intensity of the malignant symptoms, and, at the same time, lessened the number of micrococci in the blood. We examined the blood and determined the number of micrococci present; the child was then placed upon full doses of whiskey, and examination of the blood then showed that the number of the micrococci had sensibly diminished, and that they seemed paralyzed in their development. They did not have that tendency to duplication which they had before shown. These investigations were continued by Mr. Oliver Hopkinson, at my suggestion, and he has obtained some extremely interesting results. I might as well state here that we are not able to distinguish under the microscope the different varieties of micrococci, as they present exactly the same appearance; still we may say that the micrococcus of diphtheria may differ from that of erysipelas or of measles, but that, though the virulence differs in each case, they are all affected, more or less, in their development by the administration of this same drug. Dr. J. G. Richardson very happily illustrated this point before the Philadelphia County Medical Society. He said that although these growths appeared exactly the same under the microscope, yet they could not be considered on that account as being the same; the spermatozoa of a colored man and those of a white man may look exactly alike under the microscope, yet we know that the spermatozoa of one would not produce the other, and we can illustrate it further by adding that they would succumb alike to the same toxic agents.

From the experiments to which I have alluded, we may conclude that any thing that will kill or retard the growth of these micrococci has the effect either of so paralyzing them as to prevent them from producing the malignant symptoms, or else of placing the blood of the individual in such a condition as to prevent the growth of the micrococcus. We find that the fatality of the disease accords with the presence of micrococci, and that if we can destroy the latter, we can diminish the former. As I have already said, alcohol has been found to have a curative effect. The same thing has been observed in regard to corrosive sublimate. The effect of this latter remedy was marked in the experiments of Mr. Hopkinson. He also found that chlorine and chlorine compounds exercised an even more pronounced effect. These experiments are very important. It has been known for many years that the various compounds of chlorine, as chlorate of potassium, tincture of the chloride of iron, chloride of sodium, corrosive chloride of mercury, calomel and soda, chloride of lime, hydrochloric acid, and many others, had a curative or antidotal effect in these malignant conditions, or in what has been termed septicæmia. I believe that in all cases of this kind we have two different conditions; one is this tendency to malignancy accompanying the increased growth of these micrococci, which may be prevented by the use of alcohol, chlorine, and the like; the other is a septicæmia, associated with the other, resulting from a condition which is entirely different from the former, and where we have under the microscope micrococci and rod-like bacteria, due to decomposition and putridity. These latter produce symptoms of septicæmia, which are associated with those produced by the specific poison. We know that carbolic acid prevents the development of the rod-like bacteria, but it has been stated that this drug has no effect on the micrococcus. We find, by experiments on animals, that if a certain number be poisoned with the poison of erysipelas, diphtheria, they will die; while if others, poisoned in the same way, at the same time receive injections of chlorine water, they will live; and when we find that these experiments are made day after day with the same result, the logical conclusion to which we arrive at present is that, to some extent—how great we can not now say—chlorine and its compounds are antidotal to these diseases.

To review this subject, we have noted that micrococci are associated with diphtheria, that inoculation of these matters will produce the disease, that they are found at that point where the diphtheritic process is found in the greatest intensity, and lastly that certain solutions will kill or paralyze these micrococci, and prevent their growth. Let us now study a form of treatment based upon these views. We divide our treatment into the constitutional and the local. For the former we rely on hourly administration of liquid food in small quantities, such as beef-juice, wine-whey, milk, frozen beef-tea, or ice cream, albumen water, or peptonized food by the bowel; also stimulants, fresh vegetable acids, koumiss; and drugs, as quinine, strychnine, etc. We must pay a special attention to the circulation, as *heart death* may occur in two ways: first, syncope from fatty degeneration of the cardiac muscle; and sudden death, occurring even during convalescence. This requires absolute quiet in bed, digitalis, and strychnine. Second, heart clot, which is most insidious in its formation, and which, I believe, may be due to the rapidly accumulating micrococci, which can possibly be prevented by free stimulation, chlorine, and the chlorides, both internally and by inhalation, and *fresh air*. The local treatment has three objects in view, namely, the destruction of the diphtheritic poison or germ; the prevention of putridity of the false membrane, and the allaying of the inflammation of the mucous membrane itself. It is necessary for the latter indication to keep the air moist; either by the slaking of lime, to which may be added the vapor of the chloride of lime; vaporizing the throat by means of an atomizer, to which may be added opium or hyoscyamus in some form, and applying moisture to the throat without, either with a wet cravat covered with oil silk or a light poultice surrounding the neck. For the treatment of diphtheria I would recommend astringent local applications, as, for instance, the perchloride of iron, believing that the disease is originally a local affection. I would not waste time in using carbolic acid alone, for I believe that in such cases, at the onset, it is of questionable use. An excellent local application, which should be used daily by the physician, applied thoroughly to the whole mucous membrane of the fauces, is:

℞.—Tinct. iodin., ... f℥j.
Acid. carbol., ... gr. x.
Tinct. ferri perchlor., . . . f℥j.
Glycerinæ, ... ad. f℥j.

The use of the carbolic acid being to prevent decomposition of the membrane. Between times I have used a gargle of salicylic acid and claret. Common salt, I have no doubt, would be of great service, and probably the popular opinion so favorable to chloride of sodium and sulphur will be found to be based upon a very solid foundation. You know that calomel and soda, in small and frequently repeated doses, placed dry upon the tongue, has many upholders, and probably its local action is a very important one, as much so as the constitutional one in rendering the membrane aplastic. Labarraque's solution would be certainly indicated, and possibly the very valuable Platt's chlorides would serve the same good purpose.

But remember the importance of early local treatment with strong astringent applications, in proportion to the severity of the attack. The presence of false membrane will be followed by *two* evil results: mechanical obstruction, which will cause death; and its decomposition, which will produce septicæmia. These are both totally independent of the disease itself, and may be classed as complications, though in reality they are taken as symptoms.

Early tracheotomy may, but most frequently does not, prevent the former; quinine, iron, and food, with local antiseptics may ward off the latter, provided the hidden and unapproachable recesses of the nasal cavities do not render local treatment impossible, and constitutional supporting treatment unavailing. I would then give brandy in gradually increasing doses, giving it in proportion to the age of the patient and his condition, and at the same time administer chlorine in some of its forms, as tincture of the chloride of iron, or chlorine water (f℥j or less, three or four times daily, and increasing dose), which has been advocated for a long time by Dr. J. L. Ludlow, of this city, and which has been used by him with great success. I would use the vapor of chlorine in the room.

℞.—Sodium chloride, ... 7½ parts.
Bin-oxide of manganese, . . 6 "
Add strong sulphuric acid, . . q. s. (Edis.)

Dr. William Pepper recently reported a case of very severe diphtheria cured by the use of large doses of corrosive sublimate. Chlorate of sodium has been used with success by Dr. Ludlow, and is more soluble than the chlorate of potassium, and therefore more quickly enters the system. It can be given in eight or ten-grain doses every three or four hours. Here you see that the experiments in the laboratory have a practical value. They give us something tangible to work on. We find that chlorine does good; we use it and its compounds locally, freely, at first upon the mucous membrane itself, because we know that this is the initial point at which the disease originates. We try to kill or paralyze this micrococcus before it enters the circulation, for after it passes into the blood it is difficult to influence it. A curious confirmation in regard to this is found in the article by Prof. Oertel. He suggests that when the throat is very much involved, when the swelling in the connective tissue is great, when there is marked stiffness of the muscles of deglutition and great redness and the appearance of membrane on the throat, a hot poultice should be applied to the outside, for the purpose of encouraging suppuration, believing that by increasing the afflux of blood to the submucous tissue of the throat, and increasing in that way the tendency to suppuration, there is a barrier erected to throw off this poison and prevent its absorption. We cause a layer of pus to develop, and the entrance of these micrococci can be then prevented.

If the poison of diphtheria, the micrococcus of that disease, is found constantly with the epithelial detritus upon the tongue and throat and other mucous membranes, and needs but foul air, absence of oxygen, debilitated constitution, and an abrasion to awaken it from its downcast condition, why can not auto-infection take place in many cases apart from exposure to a contagium of the same kind from without? Could not membranous deposit from simple catarrh, or pseudo-membranous laryngitis with decomposition of the membrane be the exciting cause, and diphtheria be engrafted by an exciting cause from *within* as well as by bad sewerage from a faulty closet, or infected drinking water? I believe that septic or decomposing matters will rapidly vitalize the diphtheritic micrococcus in the throat and fauces, as well as in the uterus and vagina, and I also believe that apart from that the micrococcus will develop symptoms of malignancy independent of septicæmia alone. In the former iron, quinine, alcohol, and chlorine compounds should be used largely internally, and carbolic acid as an application, with a free supply of oxygen and nourishment; in the latter cases, alcohol, nourishment, fresh air, the chlorine compounds, and vegetable acids are your sheet-anchor —with local astringents.

Although these points which I have brought before you to-day are the results of theory, I should not have presented them if they had not been confirmed by practice. We know that these various compounds of chlorine have been used with good results, and we simply endeavor to connect the theory and the practice, to show why these remedies have proven of benefit.

ORIGINAL ARTICLES.

CLINICAL REMARKS ON SEVERAL CASES OF PANCREATIC DISEASE.

BY WILLIAM PEPPER, M.D., LL.D.,
PROVOST AND PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

(Concluded from page 681.)

TUMORS and degenerations of the glandular tissue of the pancreas are the lesions of this organ most frequently demonstrated at autopsies. Indeed, judging from the great frequency with which I have met with both of these lesions, they must be of really common occurrence. Cirrhosis, or fatty degeneration, of the pancreas will often be found as an associated lesion in cases of similar disease of the liver or kidneys; cancer not rarely attacks the pancreas, even in early life. The youngest patient in whom I have seen it was a boy of 12½ years, who, apparently in consequence of an injury to the abdomen, had a rapidly growing encephaloid cancer of the pancreas, involving also the left kidney and the transverse colon. The vomiting in this case was the prominent symptom, no nutriment being retained; and I am led to remark this because I have lately seen several times the statement that an absence of gastric symptoms is a point in favor of implication of the pancreas in studying cases of obscure abdominal disease. My own experience would certainly not corroborate this statement; since I have too often noted vomiting, even of frequent and uncontrollable character, in pancreatic disease, to allow me to consider its absence,

though it undoubtedly is absent in some cases, of any diagnostic value. But frequent as these forms of pancreatic disease are, it seems to me that simple catarrhal inflammation must be of vastly more common occurrence, although, for obvious reasons, it is difficult in many instances to determine its existence. It cannot scarcely be otherwise when we come to consider the extreme frequency of catarrhal inflammation of the duodenum and bile-ducts, and the close anatomical and physiological relations of the pancreatic ducts with these parts. There are indeed on record a sufficient number of fatal cases of chronic pancreatic catarrh, with the fullest development of secondary lesions of the gland, to show that even the worst forms of this disease are not extremely rare. The symptoms in such cases (of which a most interesting unpublished one, communicated to me by my friend, Dr. R. G. Curtin,[1] might serve as a type) are dull, deep-seated pain in the region of the pancreas, with occasional attacks of sharp, or even severe colicky pain; gastric derangement; intestinal indigestion; diarrhœa, with slippery stools, or with free oil in the stools; emaciation and anæmia; occasionally diabetes or œdema. It is probable that the colicky attacks are at least occasionally due to the passage of small concretions through the pancreatic duct into the duodenum. In milder forms of catarrh, however, the symptoms must be much less severe, and I have no doubt that many cases of pancreatic catarrh are overlooked or are regarded as cases of gastro-duodenal or duodeno-hepatic catarrh. Such cases we should naturally expect to be attended with a clean, moist tongue, epigastric distress, occasional sharp abdominal pain, intestinal flatulence, with tendency to diarrhœa, and absence of jaundice or of enlargement of the liver. Careful examination would probably show an undue proportion of unaltered fat in the stools; and when the swelling of the mucous membrane is sufficient to close the main duct there may be temporary diabetes.

Pancreatic catarrh may occur in an acute form, or it may run a chronic course. In the latter case it undoubtedly constitutes the lesion and essential cause of a certain number of those troublesome cases attended with chronic intestinal dyspepsia, persistent leanness despite correct regimen and careful feeding, and a tendency to looseness of the bowels on the slightest provocation. It has occurred to me also that chronic pancreatic catarrh is at the root of some of the cases of mild intermittent diabetes, which are not rarely met with. I am now engaged in studying two cases where, with the occasional increase in percentage of glucose in the urine, there is temporary loss of weight, and intestinal dyspepsia, with tendency to looseness of bowels. I am anxious to determine if at such times there is an undue amount of unaltered fat in the stools.

We are very familiar with the close and reciprocal relations between catarrhal inflammation and calculous affections of various parts, and it is not only in cases of catarrh of indeterminate location that the possibility of pancreatic implication should be carefully considered, but also in that large and often obscure class of cases where repeated attacks occur, of severe colicky pain about the epigastrium, without jaundice, and where no gall-stones are discoverable in the stools. The following case, of very recent occurrence, may be cited in illustration:

CASE III.—Mr. ——, 45 years of age, a man with large responsibilities, but who took care of himself and was rather fond of good living, had his first spell of colic while abroad. It came on suddenly, with intense pain in the epigastrium, vomiting, coldness of the extremities, and a feeling of collapse. The attack was very severe and lasted several hours; it was followed by weakness, but by no jaundice or discoloration of the urine. A second similar attack occurred in 6 months, a third about 4 months later; and thereafter they occurred for a number of months with varying severity, and at gradually lessening intervals, until he had an attack every two or three days. The pain in all cases was of the same character—acute, sharp, cutting, or tearing; and in the same locality—deep-seated in the epigastrium and through to the back. Nausea and vomiting often attended, and there was always a haggard, pinched expression of face, with cold extremities. At no time was there the least jaundice or discoloration of the urine, and the feces were not pale. The bowels were usually constipated; no free oil was ever noted in the stools; and several careful examinations of the feces for calculi failed to discover any. Careful palpation of the abdomen failed to reveal any tumor or enlargement of any organ, and there was undue tenderness only at one point corresponding to the position of the head of the pancreas, and developed only by deep pressure. There were marked anæmia and loss of flesh, and the complexion assumed an earthy, slightly sallow, cachectic look. The digestive power was much impaired, and the amount of food that could be taken was of necessity gradually reduced, until the diet consisted of small quantities of butter-milk, skim-milk, or broth, at short intervals. Under a course of this diet, with strict rest in bed and the internal use of a pill of nitrate of silver and opium, and subsequently of quinine, belladonna, and arsenic, gradual improvement occurred, and for nearly five weeks there was no spell of pain, while the power of taking food improved decidedly though slowly, and there was a gain in general condition. Without adequate cause, however, there was a return of severe spells of pain, occurring at intervals of one, two, or three days, and at varying hours, and without any fixed relation to the indigestion of food. The attacks lasted over a period of about two weeks, toward the close of which time the pain was very severe and almost constant, and scarcely any food could be taken; the loss of flesh during this time was remarkably rapid. After reaching a state of great intensity, there was a quite sudden decrease and disappearance of pain; and in a few days solid food could be taken. The patient left bed, and was soon able to go out and to gradually return to business. He continued to improve, though digestion

[1] It formed the basis of a paper read by Dr. Curtin before the Pennsylvania State Medical Society, in 1882, at Lancaster.

remained somewhat weak and sensitive, for nine or ten months, when a single isolated attack of great severity again occurred in the summer of 1882, while he was abroad.

All of the attacks in this interesting case were of similar character, and the differential diagnosis seems to possess no little difficulty. In many respects the case resembled one of gastralgia, and in default of my ability to actually prove it otherwise, this view may be entertained by some. There are various points, however, on which a different opinion may be based. The extreme suddenness and violence of the first attacks, their isolated and widely separated occurrence, and that too under unusually favorable hygienic conditions, which would have rendered the onset of gastralgia at that time unlikely; the absence of regularity as to time of day, or as to relation to the hours of taking food; the obstinate recurrence of the spells despite careful diet and treatment; the sudden reappearance of a violent attack after four weeks' absence, while the patient still continued in bed and upon careful diet; the abrupt cessation just when apparently most violent and continuous; the sudden reappearance, after nine or ten month's freedom, of a single isolated attack; the absence of gastric symptoms in the intervals of the attacks; all of these point rather in the direction of a calculous disorder than of gastralgia. It is certain that if with these attacks there had been recurring jaundice, and if the pain had been rather higher and more to the right, the character of the spells and the course of the case would have made the attending physician, Dr. Dunton, and myself confidently suspect the presence of numerous gall-stones. Indeed, it cannot be regarded as impossible for such to have been the case. I have several times seen repeated attacks of hepatic colic of marked severity where no jaundice followed, and no gall-stones were discoverable in the stools. Such cases have depended either on the passage of fine biliary gravel too small to occlude the duct or to be found in the stools, or on the presence of a single large rounded calculus incarcerated in the gall-bladder, and producing occasional attacks of colic by becoming temporarily engaged at the opening of the cystic duct. These conditions have been verified by post-mortem examinations in the cases above referred to. But further, I have recently had shown to me twelve or fifteen small pyramidal calculi, evidently of hepatic origin, which had been found in the stools of a middle-aged woman after a series of attacks of severe colic, in which the pain was referred exclusively to the epigastrium, and which were unaccompanied by the slightest tinge of jaundice, apparently because the comparatively small size and the pyramidal shape of the calculi had not allowed the occurrence of sufficient obstruction of the common bile-duct while in transit.

While, however, it is not impossible that the passage of small biliary calculi may have occasioned the successive attacks in the case here reported, I am forced to consider whether their real cause may not have been the presence of one or more large or of numerous minute pancreatic concretions. When we consider the anatomical arrangement of the pancreatic duct and its close relations with the duodenum, as well as the composition of the secretion of this gland, it seems impossible not to believe that pancreatic calculi are of far more common occurrence than is usually received. The great majority of biliary calculi are undoubtedly formed in the gall-bladder, but still a considerable number of concretions occur in the minute bile-ducts. So, while the absence of any similar reservoir in connection with the pancreas must explain the comparative rarity of pancreatic concretions, the arrangement of the minute ducts, the liability of the flow of the secretion to be retarded by narrowing of the main duct from catarrh of its mucous membrane, and the character of the secretion itself, must lead, in not very infrequent instances, into the formation of concretions in the small ducts. From the valuable inaugural thesis of my friend and former student, Dr. George Woodruff Johnston (Univ. of Penna., 1882), in which are tabulated the results of an exhaustive study of the literature of pancreatic concretions, it appears that, including the case to be reported hereafter, there are only 35 cases known where the presence of such a concretion has been demonstrated by post-mortem examination. In most of these cases the concretion was large, and had contributed in large measure to the fatal result; and I do not feel that we can draw any conclusion from the above figures as to the frequency with which minute pancreatic concretions have been passed during life, or have been imbedded in the gland and not discovered in the post-portem examination, which so rarely includes careful examination of this gland. In cases of large concretions, usually associated with enlargement, cystic dilatation, chronic inflammation, or other grave organic change in the gland, the symptoms have been very varied, embracing pressure on the vena cava, with production of œdema and ascites; jaundice from pressure on the common bile duct; gastro-intestinal derangement, with vomiting (occasionally bloody) or diarrhœa, sometimes with fatty, sometimes with bloody, stools; or more rarely with constipation; diabetes in some cases; emaciation and anæmia; dull, deep-seated pain in the epigastrium, and occasional spells of sharp, colicky pain; tenderness on pressure; a sense of deep-seated resistance or a tumor on deep palpation. In a case of simple chronic catarrh, however, with minute concretions passing into the duodenum, it is clear that comparatively few of these grave symptoms would occur. Such a case would probably present only the symptoms mentioned on a previous page, together with slight deep-seated tenderness over the site of the pancreas; some dull, deep-seated pain or sense of discomfort and occasional spells of pancreatic colic, characterized by severe sharp pain in the epigastrium, or extending thence to the back, and unattended by jaundice. Without assuming that a diagnosis of pancreatic calculi has been established conclusively for the above case, I hope enough has been said to invite attention to the possibility of such an explanation in analogous cases.

In the following interesting case the pathological condition was very complicated, so that once more the pathological affinities of the pancreas are well illustrated. The occurrence of persistent diabetes in connection with permanent occlusion of the pancreatic duct is instructive; but the numerous lesions present render any minute analysis of the symptoms unsatisfactory.

CASE IV. *Jaundice; saccharine diabetes; general atheroma and calcification of arteries; enlargement of liver and dilatation of gall-bladder, with occluded cystic duct; enlargement and cystic disease of pancreas, with large and small concretions; catarrhal nephritis; valvular disease of heart.*—Jacob Snyder died in the University Hospital, aged 62. His general health had been fair, and he had worked hard, but rather unsuccessfully. At 30 years of age, he had a bubo following a venereal sore, but no subsequent secondary symptoms. He was always sensitive to atmospheric changes, and had occasional slight rheumatic attacks. For two years previously he had been sick; at first with constipation, alternating with slight diarrhœa, but for the past ten months the stools were clay-colored, offensive, and usually costive. No report exists of any free fat detected in the stools. Up to a very late period, the appetite was good, or at times even voracious, and there was no nausea, pyrosis, or vomiting; but still he lost flesh and strength considerably. For a year there had been frequent paroxysms of sharp pain in epigastrium and right hypochondrium, radiating to the right shoulder, over the chest, and through to the back. There was troublesome flatulence, which seemed to increase the pains. Deep jaundice had existed for nine months, and for nearly the same time a slowly growing mass had been observed in the median line about three inches below the xiphoid cartilage. The emaciation was marked; two months before death he had fallen from 165 to 125 pounds. The heart's action was slow; the area of dulness was increased; there was a strong systolic aortic murmur, and also a strong presystolic murmur at the mitral orifice, and a distinct præcordial thrill. For two months prior to death, the feet were œdematous. The urine contained eight per cent. glucose, a small amount of albumen and bile pigment, but no bile acid (Pettenkoffer's modified test). The liver was greatly enlarged and indurated, and the gall-bladder was so much distended that it could readily be detected through the abdominal walls. The epigastric tumor first mentioned was distinct from this distended gall-bladder, and, although readily discoverable, was deep-seated, immovable, hard, and moderately painful. He was admitted to the hospital Sept. 5, 1879. The treatment adopted was a pill of inspissated ox-gall and ext. gentian thrice daily, and a mixture containing bichloride of mercury $\frac{1}{16}$, iodide of potassium gr. vj, tincture digitalis gtt. x, thrice daily, in water. There was a marked improvement in the jaundice, and he gained weight and strength for about three weeks; from this time he sank quite rapidly, with increasing œdema and ascites, and died Oct. 7, 1879.

The post-mortem examination revealed hypertrophy of the heart, and marked stenosis, with calcareous deposits, of the mitral and aortic valves, and intense atheroma and calcification of the aorta and smaller arteries. The abdominal cavity contained a large quantity, and each pleural sac about two pints, of clear straw-colored fluid. The liver was heavy, enlarged, indurated, and roughened, and on section showed cirrhosis with nutmeg congestion. The gall-bladder was greatly distended and dilated; the fluid contained bile, a large amount of cholesterine, pus, red blood-corpuscles, but no sugar. The cystic duct was occluded by adhesion of its walls from pressure of the diseased pancreas. The hepatic and common bile-duct were pervious, but must have been somewhat compressed during life. The minute bile-ducts were found to be dilated, and Dr. Formad found "cavernous degeneration" (Klebs) of the minute bloodvessels of the liver. No gall-stones were found anywhere. There was chronic catarrhal nephritis of the kidneys. The pancreas was extensively diseased; the head was especially enlarged, forming the tumor detected during life, and so situated as to have compressed the bile-ducts; the organ was indurated and heavy. On section of the tumor formed by the head of the pancreas, one large and several small cysts were found, surrounded by hard, cirrhotic tissue. The hypertrophied connective tissue between the glandular elements was impregnated with crystalline and amorphous lime salts. The walls of the cysts were composed of connective tissue, lined by columnar epithelium, showing them to be distention cysts, developed from some of the follicles of the gland. There were also small pseudo-cysts in the other portion of the gland, formed by distention of the minute branches of the pancreatic duct. The larger cysts were filled with a dark liquid, which showed under the microscope crystals of cholesterine and triple phosphates, pus, red blood-globules, columnar epithelium, and some pigmented cells; chemically neither sugar nor bile could be detected. There were some small pancreatic concretions in these cysts, and in one place a branching distended portion of the duct was completely occluded by a large branching calculus, which is accurately represented three times the natural size in the accompanying wood-cut. The pancreatic duct could not be traced to its termination either in the duodenum or the common bile-duct, and it had evidently been totally occluded for a long time.

Pancreatic calculi differ widely from gall-stones in appearance and in composition. They are light,

porous, grayish, cylindrical, branching, sometimes tubular. An analysis of one gave the following results:

Phosphate of lime,	72.30
Carbonate of lime,	18.90
Phosphate of sodium,	trace
Animal matter,	8.80
	100.

Such calculi have been known to escape into the duodenum; or by rupture of a cyst to escape into the abdominal cavity, or to be discharged from an abscess pointing in the lumbar region. It seems to me altogether probable that, in this case, several minute concretions may have passed into the duodenum at an earlier period of its history, explaining, in the absence of gall-stones, the paroxysmal attacks of pain. In this connection, allusion may be made to Case III. My space will not permit an adequate discussion of the interesting question of treatment involved in such cases as are here reported. It would include a consideration of the careful hygienic and therapeutic course required for the successful management of cases of duodenohepatic catarrh; together with those special dietetic precautions by which may be obviated, as far as possible, the ill results of partial or complete interference with the flow of the pancreatic secretion into the bowel.

DIABETES MELLITUS FOLLOWING ABSCESS OF THE GALL-BLADDER; DEATH FROM COMA.

By GEORGE S. HULL, M.D.,
of Chambersburg, Pa.

In December, 1879, I was called to see Mr. A. S., a tailor, and found him suffering with severe pain in lower right hypochondrium. He described the pain as burning, throbbing, and occasionally lancinating. It dated back a number of weeks, and had been increasing in severity daily, being accompanied by continued fever and progressive emaciation. At this time he was wasted in the extreme, with a quick, small pulse, and an evening temperature of 101°. Appetite was poor and bowels very much constipated. He was not cachectic, nor could any family history of carcinoma be elicited. Upon examination, there was found quite a bulging over lower right lobe of liver, the swelling having a smooth, hard feeling. Poultices were applied, and quinine and nitromuriatic acid administered; the bowels being regulated by pulv. glycyr. comp. Nourishing foods, chiefly milk and beef-tea, were given freely. The patient held his own for several weeks, when, the swelling having increased considerably, some distant fluctuation could be detected. The aspirator was used, and about an ounce of thick, grayish muco-pus was with difficulty removed. Poultices were reapplied, and in a few days a deep incision made over the point of puncture. The pus flowed readily, though the amount contained in the abscess was not very great. The patient began immediately to improve, and soon regained his usual weight and resumed his occupation. However, the opening into the abscess refused to close, and kept oozing a pale, thin, sticky fluid. This did not give him any inconvenience other than the keeping of some absorbing material over the orifice. Occasionally the discharge would cease for a day or two, when he would complain of a burning pain, which was readily relieved by the application of a poultice, the discharge reappearing. A probe could be passed into the sinus but a short distance when it was arrested by a deflection which could not be followed. Palpation revealed nothing; the surface of the liver was smooth and its size seemed normal. Although the abscess was near the region of the gall-bladder, nothing of its contour could be felt, and no trace of bile could be found in the discharge.

About one year after this illness the man, who had been pursuing his business actively, often boasting of his good health, came to consult me about some "bladder trouble," which he said had been annoying him for some weeks past. He micturated very frequently, especially at night, and passed large quantities of water. His tongue was pasty and slightly coated. He complained of his mouth being dry, and of a burning sensation in his stomach, compelling him to drink large quantities of water; said he was feeling weak, especially in the limbs, and that the weakness and other symptoms had been coming on gradually during the last month or two. His appetite was fairly good and his bowels regular; no fever was apparent.

An examination of his urine showed it to contain a trace of albumen and a large quantity of glucose, its sp. gr. being 1030, and the amount voided daily about ten pints.

He was put upon the usual diabetic diet, and given ¼ gr. calcium sulphide four times daily. After taking the remedy five days, during which time his urine was steadily decreasing in amount, and in sp. gr. also, he became so nauseated by the unpleasant eructations that it had to be discontinued. Fluid extract of ergot was substituted, and only given a couple days, when a sudden fever lighted up, the temperature reaching 102½° at night. There was also an increase in amount and density of the urine. Tincture of aconite root was given in three drop doses every two hours, the ergot being withdrawn, and in twenty-four hours the fever had left and did not return. The urine was again tested and found to contain no albumen, and but a trace of sugar, the amount passed, however, was double that of normal. The aconite was continued several days, thinking it might have been influential in causing the sudden disappearance of the sugar, etc., but the result was disastrous, the urine in two days rising in sp. gr. to 1032, and in amount to twelve pints daily. He was now prevailed upon to take the calcium sulphide again, and it was given in ½ grain doses every three hours. In three days he was passing about nine pints daily, having a sp. gr. of 1019. Bowels regular; tongue still dry; feeling brighter. Sulphide reduced to ⅓ grain every three hours.

Jan. 14.—(Two days later) eight pints; sp. gr. 1020.

16th.—Seven pints, sp. gr. 1016. But a slight trace of glucose by Fehling's test; no albumen. Tongue becoming moist. Calcium sulphide ¼ grain four times a day.

21st.—Sp. gr. 1020, but little above the normal amount. Tongue moist; appetite very good; gaining strength.

24th.—Sp. gr. 1019; amount normal, Discontinued sulphide, which had produced no disagreeable symptoms this time, the patient bearing cheerfully with the unpleasant taste and foul eructations, when he realized what good it was accomplishing for him. For one week after stopping the medicine the diabetic regimen was enforced, and then a gradual return to ordinary diet allowed. There was no reappearance of any of the symptoms, and he soon regained his usual weight and applied himself again to his trade. During this attack the sinus discharged the usual amount of thin mucus and gave him no uneasiness at all.

On the evening of April 12 (seventy-eight days since last treatment) was called to see Mr. S. He had been working unusually hard for a couple of weeks past, in order to start his son in business. Found his pulse 100; temperature 102°; skin and tongue dry; face flushed; occasional slight chills; no pain; no increase in amount of urine. The flow from sinus had ceased and to this he attributed all his symptoms. Aconite was freely given and a poultice applied to side. Although the urine contained neither glucose nor albumen, yet, fearing a return of the glycosuria, ¼ grain calcium sulphide was ordered to be given four times a day.

April 13.—A.M. Pulse 90; temperature 100°. Urine rather scanty; no sugar; no albumen. Feeling better. In the evening had several light chills, and fever rose to 102°; pulse 110. Aconite discontinued; eight grains of quinine given.

14th.—Perspired freely during night, no fever this morning. Sinus discharging again and patient feeling greatly relieved. For six days he remained free from fever and pain; complained only of great weakness. As there was no increase in the amount of urine and no sugar present, the sulphide was discontinued, and a more liberal diet allowed. His appetite was good, and between meals he partook freely of milk, egg-nog, etc., all of which he retained, but without adding to his strength. He now began to fail rapidly, complaining of great weakness and shortness of breath (his inspirations were deep, though hurried). He seemed very anxious, occasionally restless; had no pain whatever, although his groanings were loud and frequent. He conversed but little; had no fear of death, though he seemed to realize his hopeless condition. Even at this time his urine contained neither sugar nor albumen, nor was any fever present, although his pulse was rapid. He took freely of stimulating drinks, yet gradually sank into coma, which deepened till it ended in death.

A general *post-mortem* examination was not allowed, only permission given to examine the seat of abscess. Accordingly, seven hours after death, the abdominal cavity was opened. The gall-bladder was found adherent to abdominal wall, omentum and a portion of the small intestine. A probe inserted at external opening of fistula (which was three inches to right and one inch above umbilicus) was pushed with difficulty through a tortuous route of three inches into the gall-bladder, where it impinged against a hard substance. The gall-bladder was opened and found to contain fifteen gall-stones, varying from the size of a grain of wheat to one whose largest circumference measured 4½ inches, and whose weight, when dried, was 246 grains. Besides the stones there were present in the gall-bladder about two drachms of grayish mucus; no bile. The walls of the bladder were very much thickened and moulded closely around the calculi. There were no signs of recent inflammation; no fluid in abdominal cavity. Nothing abnormal could be detected in appearance of liver, however a section was secured for the microscope; the gall-bladder and contents were also taken. A microscopic examination of the liver yielded nothing of importance; the tissue was not stained with bile and was but very slightly fatty. The walls of gall-bladder were very much hypertrophied.

One would naturally look to the condition of the gall-bladder for the cause of the diabetes in this case, and, indeed, with good reason, in these days when so much light is being thrown upon this once "incurable disease." A thorough examination of the brain with negative results, had such an examination been permitted, would make one more positive in this opinion; however, the man had no history of injury, sunstroke, etc. etc., that would lead to any suspicion of brain disease. It is well known that disease of the cerebrum, cerebellum, and pons, and irritation applied to the floor of the fourth ventricle will produce diabetes mellitus; also is it accepted that the disease may be produced reflexly by irritation applied to the ends of the vagus in the liver, lungs, or intestines (tapeworm has been known to be the sole cause of a bad attack).

Here, with the irritation caused by the large mass of calculi, the fistulous opening into the gall-bladder and the adhesions to omentum, intestine, and abdominal wall, we certainly have a fruitful source of irritation to the ends of the vagus, and why not attribute the diabetes to the reflex irritation from these causes?

Concerning the treatment, the calcium sulphide (suggested first, I believe, by Dr. Husted) seemed to do wonders. Its withdrawal in the beginning of the treatment, on account of its causing nausea, and the substitution of ergot and aconite were disastrous, the patient soon becoming worse than at first. However, upon resuming the sulphide, its good effects were soon again manifested, and the patient *cured*—unless the fatal attack, nearly three months later, could be called *diabetic coma*, in spite of the absence of sugar from the urine. The term diabetic coma, however, embraces so much that we might indeed bring this sudden death under its far-reaching appellation. If acetonæmia be the sole cause of the coma, there were no striking symptoms of its presence in this case. The blood was not examined for acetone, but the breath had no characteristic

odor, nor had the cadaver when opened. If, however, diabetic coma be due to some lesion of the sympathetic system (as suggested by Teschemacher) causing *shock* from reflex paralysis of the vaso-motor nerves, the symptoms were striking indeed.

After months of hard labor, especially mental, the patient, a poor man, finally succeeded in establishing his son in business; then, the strain being over, found himself exhausted; rallied a little, then rapidly sank into coma and died—very much indeed as a man would die from the shock consequent upon a formidable surgical operation.

MEDICAL PROGRESS.

INOCULATION IN PANNUS.—DR. LOUIS L. SEAMAN reports that at the Charity Hospital the ophthalmic surgeons have resorted to inoculation in six obstinate and exaggerated cases of pannus, with the following results: First patient, totally blind in both eyes for several years was inoculated with gonorrhœal pus; discharged in April last, at his own request, as he desired to get work; vision in one eye 10-200, and 2-200 in the other. His sight has undoubtedly doubled since, though every effort to find the party has been unsuccessful. This patient had an attendant for some years previously and had been most of the time under treatment. Second and third patients had perception of light in one eye, while with the other, each patient could count fingers at the distance of a foot (1-200). Both were inoculated with a traumatic urethral discharge, which ceased after ten days' treatment. The purulent ophthalmia was very severe in all four eyes and continued for seven weeks, during which time the patients had a special nurse, night and day; and though in open ward, they were successfully secluded from the other patients by means of screens. The results of the inoculation were as follows: Second patient, right eye with white leukoma (large iridectomy previously made) and partial pannus; vision, 6-100; left eye, 12-100. Third patient, right eye, vision, 20-100; left eye, perforated cornea and perception of a moving object at a distance of two feet. These results are worthy of consideration, though the procedure is confessedly severe.—*Report of Ophthalmic Division of Charity Hospital, Blackwell Island*, 1882.

ABNORMAL DISTRIBUTION OF ARTERIES AT BASE OF BRAIN.—Abnormal arrangement of arteries in the circle of Willis is rare. At a recent autopsy such an irregularity was noticed by S. G. WEBBER, M.D. The two anterior cerebral arteries came so near each other that the anterior communicating artery was only about one line in length. The right posterior communicating artery was only about one-tenth the usual diameter, the right posterior cerebral artery was twice the usual size, or larger. The left posterior communicating artery was nearly twice the usual size, and virtually was the origin of the posterior cerebral; the left posterior cerebral was about half the usual size until it met the posterior communicating. Thus the region supplied by the right posterior cerebral artery received very nearly all its blood through the basilar; that supplied by the left posterior cerebral artery received more than three-fourths its blood through the left carotid. The right posterior cerebellar was so small that it could not be distinguished from other small and terminal arteries. Its place was taken by one of the branches from the basilar, which was larger than usual, and, after passing backwards and upwards over the surface of the cerebellum, curved forwards and downwards to occupy the normal position of the posterior cerebellar between the cerebellum and medulla. The basilar artery was rather longer than usual, the vertebrals uniting at a lower level than normal. The middle cerebral arteries and the anterior cerebellar arteries were normal.—*Boston Medical and Surgical Journal*, Dec. 7, 1882.

FRACTURE OF THE CRICOID CARTILAGE.—DR. MASUCCI reports a case of fracture of the cricoid cartilage followed by cure. The rarity of this lesion and the conflicting accounts as to the mechanism of its production, led him to make a number of experiments on cadavers and dogs, in which the various conditions were imitated in which this lesion could be produced. He found that to produce a fracture of the laryngeal cartilages, a certain degree of ossification must be present, and the larynx must be fixed by muscular action, the blow or violence must be on the larynx directly from before backwards, and not obliquely or laterally; otherwise the larynx will be displaced and not fractured. Asphyxia and aphonia are constant symptoms, and the former, unless treatment is energetic, will be the cause of death: crepitation, emphysema, and dysphagia are also present, with the other signs of violence, such as ecchymosis, œdema of the neck, etc. M. Masucci also observed a condition of convulsive trembling of the sub-hyoid muscles.—*Rev. Mens. de Laryngol. d'Otol. et de Rhinologie*, November, 1882.

TWO SUCCESSFUL CASES OF CHOLECYSTOTOMY.—MR. LAWSON TAIT reports the following cases. The first was that of a lady aged 28, with obstruction of the cystic duct from gall-stones. The abdomen was opened by a vertical incision over the tumor, which proved to be the distended gall-bladder. He emptied it by the aspirator, removing about a pint of thick glairy mucus. He then laid it open, and removed about eighty gall-stones of small size, the largest weighing fifteen grains. They were removed chiefly by the use of a *curette*.

He then stitched the aperture in the gall-bladder to the wound in the abdominal wall, carefully closing the peritoneum, and leaving a drainage-tube in the gall-bladder. The patient's recovery was uninterrupted; the highest temperature recorded was 100.4°, and the highest pulse record 84. The stitches were removed on the eighth day, the drainage-tube on the twentieth day, and in ten days more only a small sinus was left, from which some mucus still continues to be discharged. The patient has gained flesh since the operation, and has been entirely free from pain.

Neither at the operation nor in the after-treatment were any of the "antiseptic" methods of Prof. Lister employed.

The fistula in the gall-bladder continued to discharge clear mucus till on August 5, when "something seemed to give way," as she said, and bile flowed freely. This shows that the occlusion of the duct had been overcome, and the complete functions of the organ may be re-established by the closure of the fistula.

The second case was that of A. B., aged 37, who was placed under his care some weeks ago by his colleague Dr. Hickinbotham. A tumor in the position of the gall-bladder could be occasionally discovered, and she suffered intermittently from severe attacks of colic. It was clearly a case of distended gall-bladder. On October 13, he performed an operation precisely similar to that narrated above, and removed sixteen gall-stones, varying from seven grains to thirty-five in weight. He removed the drainage-tube on the third day. The stitches are now (October 24) all removed, and the wound is almost healed.—*British Medical Journal*, November 18, 1881.

Demonstration of the Bacillus Tuberculosis in Sputa.—Dr. Hlava recommends the following method as especially applicable to the detection of bacilli in tuberculous sputa: Fifty grammes of fuchsin or methyl-violet solution are poured into two hundred grammes of alcohol, and allowed to stand twenty-four hours, and then filtered. A saturated solution of oil of cloves is then prepared, which must remain cloudy and of a dirty yellow color; it is then filtered, and a few drops of the fuchsin solution added, so as to form an opalescent solution. The sections are allowed to remain in this solution for thirty minutes, and decolorized by a mixture of nitric acid and water, 1 to 5; they are then washed in water or alcohol, cleared with oil of cloves or glycerine, and mounted in Canada balsam or glycerine cement. Sputa are prepared as directed by Koch, and stained as above, with the exception that a mixture of equal parts of nitric acid and water is required to remove the excess of color. The bacilli are by this process stained either red, violet, or blue.—*All. Wiener Med. Zeit.*, Oct. 31, 1882.

Croup and Diphtheria.—Prof. E. Henoch draws attention, by means of a paper published in the *Berliner klinische Wochenschrift* of Oct. 2d last, to the difference which, according to his view, exists between the non-specific croupous angina and true diphtheria, diseases which he believes are not sufficiently discriminated. At the outset he expresses his conviction that there is such a thing as a non-specific croupous pharyngitis, and he regards croup as only being identical with diphtheria, whether in its pathological or other relations, in the same way as a smallpox pustule resembles a pustule produced by vaccinia or as the result of the inunction of tartar emetic. Any so-called croup having a specific origin is, he alleges, diphtheritic. With a view to the better distinction of the two diseases, he points out that the non-specific croupous pharyngitis is generally characterized by the suddenness of the febrile invasion, whereas in diphtheria the fever is at the onset only slight and insidious in its progress. A much less constant difference lies in the fact that in the non-specific disease a single tonsil is, in the first instance, much more frequently affected than is the case in diphtheria. So also the extension of the membrane to the palate, and especially to the back of the pharynx, must always be regarded as highly indicative of true diphtheria, and the implication of the mucous membrane of the nasal passages is a certain sign of that specific disease. On the other hand, certain indications to which importance is at times attached are, according to Prof. Henoch, comparatively unimportant. Thus albuminuria, generally regarded as a symptom of diphtheria, is often absent in undoubted cases of that disease, and micrococci, when discovered by the aid of the microscope, are of little value for the purposes of diagnosis, not only because they are found everywhere in the mucous membrane about the pharynx, but because no definite microphyte has been shown to be associated with diphtheria. The difficulty attaching to a correct diagnosis should, however, in the author's opinion, never interfere with measures of prevention, and hence he urges that where there is the least doubt as to which disease is being dealt with, isolation should be rigidly enforced.

Prof. Henoch proceeds to point out that the disease known as scarlatinal diphtheritis is essentially distinct from specific diphtheria, and, according to his experience, the failure to distinguish between them is largely due to the fact that scarlatina and diphtheria are often treated in the same wards, and that patients whilst convalescing from the one contract the other. Cases are cited to show how patients recovering from scarlet fever associated with marked throat lesions have contracted true diphtheria, and it is further shown that in patients who have undergone the operation of tracheotomy for diphtheritic croup, scarlatina with throat ulceration has subsequently intervened, the reception of the scarlet fever being greatly facilitated both in such an instance and in the case of convalescence after extensive diphtheritic throat lesions by the fact of the exposure of a wounded surface to that scarlatina poison. In such instances it is, however, suggested that a correct diagnosis will be aided if it be borne in mind that the throat ulcerations due to scarlatina follow on and do not precede the diphtheritic symptoms. In some of these instances the characteristic sequelæ of the two diseases have, in the later stage, been found mingling together in a manner which might easily be regarded as affording some proof of the unity of the disease, had it not been for the clear distinction between them which was possible at an earlier period of the patient's illness.—*Lancet*, Nov. 18, 1882.

The Treatment of some Chronic Gastric Disorders.—M. Broca, in a series of articles (*Le Progrès Médicale*, 39–42), strongly advocates, in ulcers of the stomach and chronic gastritis from various causes, the systematic washing out of the stomach and artificial feeding. In washing out the stomach there are two indications to fulfil—one, to empty it of its contents, whatever they may be; and the other, to treat the diseased mucous membrane with medicated solutions. He advocates the use of the siphon tube, on the ground that its manipulation is so easy that in a very short time the patient can learn to wash his stomach out himself. The washing over, the patient should be fed before the tube is withdrawn, powdered meat, raw eggs, milk, or broth being the most suitable food. He lays great stress on the advantages of over-feeding the patient, and mentions six hundred grammes of raw meat, a dozen eggs, and three litres of milk as a daily allowance that may easily be exceeded. It is always necessary to commence gradually, until it is ascertained that the patient can digest milk and eggs well. Should pain come on some hours after the meal, it is advisable to empty the stomach by means of the tube. The cure is permanent if the patients only take proper care of themselves afterwards. He thinks that this mode of treatment might with advantage be extended to other cases than purely stomach disorders; he suggests it, for instance, in advanced phthisis.—*Medical Times and Gazette*, November 18, 1882.

The Action of Quassine.—Dr. Comparden finds that quassine, the active principle of quassia amara, in moderate dose produces an increase in the salivary, hepatic, and renal secretions, and acts as a stimulant to the muscular fibre of organic life. In doses of 15 milligrammes to 15 centigrammes, it causes in man a burning pain in the œsophagus, headache, nausea, vertigo, dimness of vision, vomiting and diarrhœa, and cramps of the muscles of the leg. These symptoms are removed by chloral or chloroform.—*Bull. Gén. de Thér.*, November 15, 1882.

Treatment of Enlarged Tonsils.—When excision cannot be performed, Dr. Gordon Holmes mentions the following as a very effective method of applying the common caustics to the tonsil, which appears to have remained hitherto unnoticed. The tonsil, as the anatomist knows, is permeated by several rather large channels around which the follicles are collected, opening on the pharyngeal side of the gland, whence its characteristic cribriform aspect. Their orifices, about seven to fifteen in number, are sufficiently evident to be counted on the healthy tonsil *in situ*, whilst

in the hypertrophied condition these lacunæ increase greatly in calibre and depth, and can be ascertained by a probe to vary from one-eighth of an inch to half an inch in length, with a diameter capable of admitting a style of ordinary size. These observations, then, afford a valuable indication for treatment: for through these natural canals a way lies open for us to attack the heart of the gland in a most efficacious manner with our caustics. Thin, pointed sticks of nitrate of silver or chloride of zinc can easily be pressed into the lacunæ and worked round for a few seconds. Small sloughs are thus formed, which are soon discharged, and in the progress of this treatment the tonsils are hollowed out in one direction whilst being contracted into much smaller bulk by the subsequent cicatrization in another. Two or three channels in each tonsil can be cauterized daily or on alternate days, and we can thus act on a comparatively large surface whilst causing but slight external soreness and little or no suffering to the patient. In practising this method, although the stronger caustics may be used, he does not think it will be necessary to have recourse to anything more potent than nitrate of silver, which acts much more effectually on the tender internal structures of the tonsil than when applied to the comparatively callous pharyngeal surface.—*Lancet*, November 11, 1882.

Extirpation of a Cyst of the Mesentery; Recovery.—Werth (*Arch. f. Gynäk.*, xix., 2, 1882) reports the case of a patient who happened to notice an abdominal tumor during an attack of colic, three months previously. The tumor was of the size of a child's head, very movable. Soon after W. had examined the woman, the tumor became incarcerated in the pelvis, causing great pain, vomiting, and general prostration. Laparotomy. The tumor was imbedded between the two layers of the iliac mesentery, and was easily enucleated. Recovery. The contents of the cyst were of the consistency of thin gruel, not unlike a suspension of chalk in water. Microscopically nothing was found in the contents of the cyst but albuminous and fatty detritus. The wall of the cyst showed a distinct lamellar structure. W. failed to find epithelial cells, the predominant structural elements being those of the connective-tissue type. As to the nature of the tumor, W. thinks that it was a mesenteric gland transformed into a cyst.—*American Journal of Obstetrics*, December, 1882.

Etiology of Croupous Pneumonia.—Griffini and Cambria have been working at the question of the etiology of croupous pneumonia, and an abstract of the results of their investigations is given in the *Centralblatt für klinische Medizin*, No. 25. There is, they conclude, a bacillus in the blood and sputa of pneumonic patients, which is not the same as Klebs' *monadin*. When the pneumonic sputum, free from saliva, was subcutaneously injected, or placed in contact with the trachea of rabbits and dogs, a fatal form of septicæmia was induced, and the blood of these dead animals when inoculated into others led to a lethal result. The authors maintain that this is not a specific effect of pneumonic sputa, for some old experiments by Senator have shown that the inoculation of fresh bronchial mucus under the skin of a dog was followed by a deadly result. The saliva of pneumonic patients kills rabbits rapidly, but only gives rise to an abscess at the site of injection in dogs. Defibrinated blood from cases of pneumonia, thrown into the cavity of the peritoneum or of the trachea of rabbits and dogs, resulted not in pneumonia, but in various degrees of fever. Inoculations of the bacilli in various stages of artificial cultivation never caused any changes in organs, but only alterations in temperature. The bacillus of the pneumonic blood and sputa was always afterwards found in the blood of the vaccinated animals, although it had excited no pneumonia; hence, the authors believe that the bacillus found in the patients suffering from pneumonia was an epiphenomenon, and not a necessary factor in the production of pneumonia. When small doses of ammonia were syringed into the trachea of animals, lobar pneumonia was invariably produced if the animals survived a few days. The authors come to the conclusion that pneumonia is not an infectious disease—*Medical Times and Gazette*, November 25, 1882.

Color-blindness.—Dr. Kolbe, one of the several Russian physicians who have been engaged in a series of important researches in connection with color-blindness, has published the results in *Vratsch*. Out of 10,828 railway servants examined, no fewer than 251 were color-blind, and 32 proved to have an imperfect capacity for distinguishing colors. The average percentage of color-blind would thus be 2.6; but the five doctors who have made these investigations arrived at very different percentages, namely, from 0.85 to 5 per cent. Three other doctors have made experiments on sailors and pupils in naval schools, and have found a much higher percentage—6.08 per cent. of color-blind, and 8.5 with imperfect vision. Among scholars of naval schools, the percentage of color-blind is, however, smaller—that is, 1.6 and 1.95. Women are subject to a far smaller extent to color-blindness. Thus, Dr. Kolbe, who has experimented both on men and women, discovered among the men 2.5 per cent. of color-blind, and 7.5 with imperfect vision; whilst among women, he has discovered only 0.16 per cent. of color-blind, and 3 per cent. with imperfect color-vision.—*British Medical Journal*, November 18, 1881.

The Value of Anomalous Respiratory Movements in the Early Diagnosis of Pulmonary Tuberculosis.—Dr. Grancher shows that more value than has heretofore been believed can be attached to the presence of anomalous respiratory movements in the early diagnosis of tuberculosis of the lungs; and, when the irregularity is localized in the apex of the lung, particularly on the left side, and is permanent, it permits of a positive diagnosis, even in the absence of other signs, such as crackling or alterations in vocal fremitus or pulmonary resonance. These respiratory anomalies, in the order of their importance, are rough and deep inspirative murmur, feeble and jerky respiratory movements; the harsh and deep-toned inspiratory murmur is the most valuable sign, as it is the earliest which appears.—*L' Union Médicale*, November 21, 1882.

Modification of Salivary Secretion by Excitation of the Sigmoid Gyrus.—M. Bochefontaine has observed that violent excitation of certain regions of the cerebral cortex is followed by a condition of complete inexcitability. The passage then of a galvanic current through a point of the sigmoid gyrus, whose stimulation was previously followed by a secretion of saliva, is then inefficacious; but this same current when passed through a point in the immediate neighborhood, then causes a flow of saliva and this point in its turn becomes inexcitable. M. Bochefontaine proposes the following explanation: denying the excitability of the gray matter, he attributes the phenomena to stimulation of the white peduncular fibres; when these fibres are excessively stimulated at any point of their path, they become inert through a small extent, but preserve their excitability through the remainder of their path.—*Le Progrès Médicale*, November 18, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, DECEMBER 23, 1882.

EMBARRAS GASTRIQUE.

IN presenting the compliments of the season to our readers, it is our hope that this issue may reach them in the full enjoyment of the pleasures of this festal time.

As a subject connected with the medical aspects of Christmas-tide, we beg to offer some observations on a malady often produced by its festivities.

Embarras gastrique is an eminently apt designation, for which we have no suitable or exact English equivalent. This malady is not less, but more common, in this country than in Europe. Americans habitually indulge more freely in the pleasures of the table than foreigners, because of the high price of labor and the cheapness and variety of our native foods. Especially at the holiday season are attacks of acute gastric catarrh common. The unrestricted indulgence in sweets allowed to children at this season, the unwonted imbibition of alcoholic fluids of all kinds by adults, and the general consumption of rich articles of diet by all classes and every age, necessarily greatly embarras the stomach. It would, however, be taking a very narrow view of the subject to limit the pathological mischief to the mere stomachal disturbance. Although perfectly well known, it is doubtful whether there is an adequate conception of the important reflex relations of the stomach entertained by physicians in general.

Besides the mere stomachal derangements characteristic of *embarras gastrique*, there are varied and important reflex disturbances. It is a well-known fact that attacks of acute alcoholic delirium, and *delirium tremens*, are far more common at and immediately after the Christmas holidays than at any other period. Convulsions, attacks of laryngismus stridulus, ulceration of the tonsils, are reflex effects observed in children under the same conditions. Cerebral hemorrhages and epileptiform seizures are amongst the more uncommon reflex accidents thus induced; whilst vertigo and hebetude of mind belong to the usual and ordinary reflex effects of *embarras gastrique*. We should not overlook the agency of stomachal derangements of an acute kind in the production of pneumonia. If we refer to the anatomical relations of the vagus, and the results of its division in animals, we can hardly doubt the effects which may follow irritation of its end organs in the stomach. The depressing effect of persistent irritation of these terminals on the nucleus of the nerve, we do not doubt, may be the needed factor to determine an attack of pneumonia when the other conditions are present. Amongst the most frequent of these reflex effects, are certain cardiac troubles. There are also mechanical effects of no small importance. Irregular action, and more or less violent palpitation, in adults, intermission of the pulse in children, are obvious reflex cardiac symptoms. Gaseous accumulation, and the consequent upward pressure of the stomach against the diaphragm, mechanically impede the play of the heart. These effects, although distressing, and often alarming, are not dangerous to life, in the normal state of the organ, but when a fatty condition of the cardiac muscle exists, and in some cases of adherent pericardium with the resulting myocarditis, in those mysterious instances of cardiac neuralgia with changes in the motor ganglia, etc., these functional disturbances assume a high degree of pathogenetic importance.

The least attentive consideration of the foregoing facts, must convince any one that *embarras gastrique* is not a trivial disorder.

The catarrhal condition of the mucous membrane is rarely, if ever, limited to the stomach. The mucous membrane of the duodenum, is implicated to a less or greater extent, and by no means infrequently, some catarrhal swelling of the orifice of the common bile-duct, and of that conduit itself, takes place. The influence of this condition in the symptomatology of the malady under consideration will be made evident, hereafter.

The symptoms by which *embarras gastrique* is recognized, are, a rather heavy or foul breath; a coated, sometimes heavily-coated, tongue; a yellowish and suffused conjunctiva; a muddy, almost jaundiced complexion; headache, dizziness, and confusion of mind; nausea, often vomiting which becomes bilious after a time; stomach pain; constipation, sometimes diarrhœa, etc. In children there may be feverishness, and in adults fever, or a

slow pulse indicating cerebral oppression. Very often, the offending substance may be recognized in the eructations, or merely in the consciousness of the patient. Lastly in some persons, especially in the case of habitual sufferers, an attack of this malady always takes the form of sick headache.

If we have not overrated the importance of *embarras gastrique* the treatment of this condition deserves careful consideration, particularly at this season when we are likely to see so many examples of the affection. The mildest cases may, it is true, need only evacuation of the stomach, but those in which the catarrhal process has invaded the duodenum, require more elaborate management. A careful regulation of the diet, including almost total abstinence for the first day or two, the stomach having been thoroughly emptied by suitable means, and the administration of a mild saline, such as a Seidlitz powder, may be the only measures necessary. The most obvious reason for thorough evacuation of the stomach, is the irritation caused by the fermentation of certain constituents of the foods. The saccharine and fatty elements, especially, undergo the acetic, lactic, and butyric fermentations, resulting in the formation of highly irritating acids. Hence it is, when the contents of the stomach come up, they are intensely acid and offensive. When acid is so much in excess, there is enough not only to neutralize the alkaline juices of the duodenum, but to give an acid, rather than an alkaline, reaction to them. After the stomach is emptied and the intestinal canal moved by a saline, an anti-ferment—if the derangement continue—renders an incontestable service. Under such circumstances, a combination of carbolic acid, or creosote with bismuth, is highly useful. An alkali, given to neutralize the acid, merely palliates, by removing the acidity for the time being, but rather favors than retards subsequent acid fermentations.

An important point in this connection is the administration of mercurials. When the conjunctiva is yellow, the complexion muddy, and the tongue has a yellowish coating, especially if there be a jaundiced hue of the skin, mercurials are supposed to be indicated. It is particularly advisable to have correct views in respect to this condition of things. Rutherford's experiments on dogs, as all the world knows, have demonstrated that calomel does not increase the hepatic secretion. Dogs are generally considered poor substitutes for men, but there happens to be entirely confirmatory evidence in the case of Westphalen's patient with a biliary fistula, on whom calomel rather decreased the flow of bile. If calomel had a stimulant effect on the liver, it would be contraindicated in these cases. It is undeniably useful, on the other hand, and because it has sedative effects. In the cases of *embarras gastrique* small doses of calomel—one-half to one-sixth grain—will allay the irritability of the stomach, and act efficiently as a purgative. The change in the character of the evacuations produced by mercurials, not due to alterations in the hepatic secretions, are too complicated to be discussed here. Whilst we may admit the fact of the change, and the utility of the treatment, we must reserve our judgment in regard to the precise nature of the process. If relief is procurable by less doubtful means than the administration of mercurials, there can be no question about the propriety, indeed the duty, of employing such measures.

WANTED—A NEW ANATOMY ACT.

The recent deplorable developments in reference to the supply of anatomical material by illegal methods, which have been followed by such swift punishment, have called attention to the exceedingly unsatisfactory condition of the law of 1867, commonly called "the Anatomy Act," for the distribution of unclaimed dead bodies. This Act provides that public officers shall deliver for dissection the bodies of deceased persons required to be buried at the public expense, said bodies to be distributed among the schools equitably in proportion to the number of their students. We take occasion, therefore, to suggest that a new Anatomy Act should be passed during the coming session of the Legislature, and to point out the alterations which seem necessary for the efficient working of such an Act. Other States may well profit by the experience of our own.

1. The present Act applies only to the counties of Alleghany and Philadelphia. Practically the Philadelphia schools have to depend on the supply derived from Philadelphia County only—a restriction both unreasonable and noxious, as the late events prove. That it is unreasonable, any one will admit, when it is considered that physicians from all parts of the State are educated at Philadelphia. During the last session at the University and Jefferson College alone, there were 547 students from Pennsylvania, the vast majority of whom came from other counties of the State than Philadelphia, and yet only the unclaimed dead of Philadelphia County are legally made available for their instruction. The new Act should make the unclaimed dead in the *whole State* available for dissection.

It may be asked whether there exists any need for an Act so wide in its application. Let the figures answer. We would scarcely let any one meddle with our watch who had but twice dissected one. It will, then, hardly be thought unreasonable that the student shall dissect and perform operations upon the human body *once* during each of the two years devoted to the study of anatomy. This would require each winter one subject to every two stu-

dents in the anatomy and operative surgery classes. Taking no account, then, of those students who would desire to do *more* than this, let us see what should be the very smallest number of subjects necessary for their reasonably thorough medical education.

During the session of 1881–82 there were in the dissecting and operative surgery classes in Philadelphia 1493 students, who under this estimate would require 746 subjects, to which number must be added about 50 for lectures and demonstrations by the professors, that is, 796 subjects. This, be it understood, is the number of subjects *required*. The number actually *used*, as we have the best reason to believe, is but little beyond one-half this estimate. The resulting restriction of the anatomical and surgical opportunities of students is no less serious than it is lamentable.

The number of subjects received from the Almshouse during that session was 302—about 40 or 50 more than the average number. To this may be added, say 93 from the Coroner, and about 10 from the prison, the House of Correction, etc., making about 405 subjects. If 796 subjects are requisite and only 405 are to be had from proper sources of supply in this County, is it not reasonable to ask that other counties assist in the medical education of their own students who come to Philadelphia, to say nothing of the students from other States. Such a statement of the utter inadequacy of the supply emphasizes also the need for an equitable distribution of the bodies legally available, not only from the Almshouse, but from all other sources.

One thing more should be said—that in spite of the great difficulty the medical schools of this city have had, in common with those in all parts of the country, in supplying the increasing number of students with anatomical material, desecration of graveyards has been exceedingly uncommon. Since 1867 when the Anatomy Act was passed, until the recent spoliations began, we have good reason to believe that rarely, if ever, have any bodies been supplied illegally.

2. The present Act says that the unclaimed dead are to be distributed among the schools *pro rata*, but no well-defined machinery is provided by law for such a purpose. The anatomists have voluntarily agreed upon a fair distribution by an Anatomical Committee, to whom stated returns are made by each school. The Board of Guardians of the Poor have availed themselves gladly of this solution of the problem, but the Coroner, though for some months in 1880–81 he acquiesced in the same plan, no longer does so, and now claims that the Act does not require him to distribute the unclaimed bodies that come under his cognizance. Indeed he states that, in accordance with his view of the law, it is his duty to have them buried, and that after he has given the certificate of death his control over them ceases. This view we cannot accept, since the law expressly devotes those bodies "required to be buried at the public expense," to the medical schools "for the advancement of medical science," and directs that "any public officer having control over them shall give permission to any physician or surgeon to take them, preference being given to medical schools, public and private." The new Act should prescribe a fair method of distribution, similar, perhaps, to that already in existence, and make it obligatory upon public officers to submit to it.

3. The present Act provides a penalty for trafficking in bodies, but omits any penalty for non-compliance with its provisions. To urge the insertion of such a penalty would be a work of supererogation.

Had the above remarks only to do with the pleasure of doctors in scientific studies it would be even then of no little moment. But it is the terrible results that must ensue to the community from imperfectly educated medical men, unless something radical and efficient be done, that make it of vital importance. The whole community is interested that its advisers at birth, sickness, and death be as skilful as possible. To be such they must know first of all the anatomy of the human body.

We hope, therefore, that immediate steps may be taken looking to prompt legislative action.

MENTAL CULTURE AND LONGEVITY.

SIR THOMAS WATSON'S career affords a signal illustration of the influence of mental culture on longevity. Notwithstanding he passed a life of incessant labor, he continued with unimpaired intellect much beyond the ordinary period of human existence. The late Dr. Jacob Bigelow, of Boston, who attained the advanced age of ninety-four, is another instance. A most interesting account of an interview with Dr. Bigelow, a short time before his death, was published by Dr. Bowditch, of Boston, in the *Boston Medical and Surgical Journal*, in which we learn that the aged Doctor had not lost that acuteness of intellect which had distinguished him during the most active period of his life. Sir Thomas Watson seems to have preserved his powers until a short time before, if not until quite up to, his last moments. There are many other examples of the combination of longevity with a high order of professional and intellectual activity, of course; but few instances of such conspicuously high mental activity, conjoined to such extreme longevity. We dwell on this aspect of Sir Thomas Watson's career the more especially to impress on our readers the beneficial effect on the bodily functions of active exercise of the mental powers. We hear much in these days of the deleterious effect of unremitting

mental toil; but what shall be said of the career of the eminent professional men who have outlived, as they outworked, the most of their contemporaries?

In the case of Watson, it was not alone education, culture, and vigor of constitution which advanced him to the highest rank in the confidence and esteem of the English people. He conjoined to an admirable *suaviter in modo* a most refined *fortiter in re*. He was, at the same time, a pleasant and cordial gentleman, and a resolute and uncompromising opponent of all mean and base practices of every kind.

DERMATOLOGICAL.

WE have constantly to lament the unkind spirit in which medical journalists refer to the work of their colleagues. It has not often fallen to our lot to record a more signal instance of this than the comments of the *Michigan Medical News* on the opinions of Dr. L. P. Yandell, Jr., in respect to the pathogenetic relations of cutaneous diseases. Dr. Yandell is one of the editors of the *Louisville Medical News*, and, also, a professor in the University. He may, therefore, be supposed to know something of the subject in regard to which he gives an opinion. The *Michigan Medical News*, actuated by that iconoclastic spirit, unhappily too much in vogue in our time, criticises these utterances of Dr. Yandell, and the latter appeals to his colleagues of the press for justice. We are deeply impressed with the magnitude of our responsibilities under these circumstances. When doctors differ, who shall decide? is the old adage. We will not presume to decide, but will submit the important questions at issue to the tribunal of medical public opinion. The Michigan paper, as quoted by Dr. Yandell in his circular, says:

"Dr. Yandell attributes all skin eruptions to malaria. Quinia is a specific for malaria; *ergo*, quinia is the remedy for all skin symptoms."

Such is the allegation. Dr. Yandell hopes that his *confrères* of the press will give publicity to his correction of the misunderstanding into which his Michigan brother has fallen. We make haste to do so. Dr. Yandell's new statement is as follows:

"Malaria is the *chief source* of *acute* skin disease. Scrofula is the *chief source* of *chronic* skin disease."

In explanation, Dr. Yandell says: "*I do not claim* that malaria and struma are the *sole* causes of the dermatoses. Indeed, *many* of the dermatoses may exist *independently* of *malaria* or *struma*."

After such a luminous exposition of his views, it is surprising that any journal should attempt to discredit his theory. If malaria and struma are, and are not, the chief pathogenetic factors of skin disease, what more can be said? In our opinion, Dr. Lunsford P. Yandell has made his point good, and has so entirely settled the question of the etiology of skin diseases that all doubters must retire from the field in confusion.

DR. BEARD ON MIND-READING.

WE find in the issue of the *New York Tribune* for Wednesday, December 13, an account of mind- and muscle-reading experiments, conducted in Dr. Beard's office. A pale, delicate boy of fifteen is the subject of experiment. Dr. Beard makes some passes, and straightway the youth goes off into the somnambulistic state. Then the mind of the operator being fixed on some particular object—a piece of paper, a pin, etc.—the youth flies about the apartment, leading his experimenter by the hand, until the object is found. Sometimes there is a failure, because the operator does not fix his mind on the object sufficiently powerfully, etc. Whilst we do not pretend to doubt Dr. Beard's sincerity, or his scientific zeal, we must protest against such exhibitions being received as of medical authority. Besides the obvious dangers of deception and fraud, there are no new facts developed by such experiments. To conduct them before newspaper reporters, and a gaping multitude of *quid nuncs*, is to lower them to the level of those performances carried on by peripatetic mesmerizers, and are, therefore, as we conceive, unworthy the attention of a truly scientific expert. We observe with regret that Dr. Beard lends himself to such questionable practices. If he wishes to so occupy himself, he ought at least divest them of any supposed medical professional character.

IN another column we publish a letter from Dr. C. R. Agnew, which, it may be presumed, is an authoritative statement of the sum and substance of the arguments advanced in defence of the new Code. From time to time these "arguments" have been fully refuted in our columns, and it seems useless to seriously consider them again. Moreover, we cannot think that any number of our profession can agree with Dr. Agnew in believing that, because the legislature of New York passes a law declaring that any one possessing a diploma from an incorporated medical school, or a license to practise, is "a legally qualified practitioner," therefore we should be so forgetful of our standard of professional requirements as to go still further, and declare that we shall receive him as one of us, and thereby recommend him to the public as worthy of their confidence and support.

By some occult process of reasoning Dr. Agnew connects the new Code of his State with the beneficent workings of the laws to regulate the practice of medicine in other States, and apparently forgets

that the old Code alone is recognized by the profession in those "twenty States and Territories," including Illinois, in which these good results have been obtained. Indeed in New York the adoption of the new Code has had no effect on the prosecution of illegal practitioners, which was just as active last year under the old Code, as it is now.

The fact is no Code of Ethics has had or ever can have any legal force, and the only good ever to be obtained by a Code is in the establishment of a recognized standard of professional morals. To ask the profession to affiliate with every man whom the State recognizes as authorized to practise medicine, is to ask the profession to yield up everything which has made it honorable since "the time whereof the memory of man runneth not to the contrary."

REVIEWS.

THE PHYSICIAN'S VISITING LIST FOR 1883. Philadelphia: P. Blakiston, Son & Co.

THE PHYSICIAN'S MEMORANDUM BOOK. Arranged by JOEL A. MINER. Fifth and improved edition. Ann Arbor, Michigan.

THE PHYSICIAN'S VISITING LIST AND DIARY FOR 1883. Louisville, Kentucky: Geo. H. Dietz & Co.

WALSH'S PHYSICIANS' COMBINED CALL-BOOK AND TABLET. Seventh edition. RALPH WALSH, M.D., Washington, D.C.

THE number and variety of the Visiting Lists now offered to the medical profession are so great as to constitute a veritable embarrassment of riches. Whilst they differ somewhat in arrangement they agree in design. In some of them, the matter of engagement making and recording is the controlling idea; in some it is accurate bookkeeping; in others, besides these objects, it is sought to impart a quantity of medical knowledge. As a general rule, these ready methods for treating diseases, are misleading. It would be extremely convenient, if the physician could carry in his coat pocket, formulated rules by which he could manage every case. Unfortunately more elaborate preparation is necessary, and hence the rules of the visiting list have little adaptability. We may make an exception in regard to the method of treating poisoning, and of resuscitating the asphyxiated.

Of the visiting lists now before us, the original model, that of P. Blakiston, Son & Co., is probably the best, and most of those in the market owe their inspiration to it. Walsh's Combined Call-book and Tablet presents some special conveniences, and is a good arrangement. It differs in respect to certain original conceptions more than any of them, from the model of them all. The Louisville Visiting List and Diary has many points of resemblance to Blakiston's, and hence is, probably, so much the better.

Miner's Physician's Memorandum Book is a rather complicated arrangement, but it may be adapted to any of the Physician's engagements or business. It is no doubt very complete, and must be useful in a high degree to those who require such a pocketbook.

Any of the "visiting lists" now offered to the profession must answer a useful purpose, and accomplish the purpose for which intended.

SOCIETY PROCEEDINGS.

TRANSACTIONS OF THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday evening, December 7, 1882.

VICE-PRESIDENT, T. M. DRYSDALE, M.D., IN THE CHAIR.

DR. T. M. DRYSDALE reported the following case of

UTERINE MYO-FIBROMA.

An unmarried lady, 31 years old, of Trenton, N. J., consulted me January 18, 1879, as to the advisability of an operation for the removal of an abdominal tumor. On examination it proved to be a uterine fibroid, hard, smooth-walled, and moderately movable. It filled the lower part of the abdomen and extended upwards to about an inch above the umbilicus. A peculiar feature in the case was the presence in the lower part of the tumor of a large vessel with an aneurismal thrill, which could be felt through the upper part of the left side of the vagina. As her general health was good, the tumor producing no inconvenience except by its size, and the menses regular in every respect, I advised against an operation and directed her to take chloride of ammonium in ten-grain doses three times a day, and, at her menstrual period, 30-drop doses of the fluid extract of ergot at the same intervals.

She continued this treatment for two years, the tumor in the meanwhile slowly increasing in size. At the end of this time, finding no diminution in the size of the growth, and becoming discouraged, she abandoned all medicines. The tumor continued to grow steadily, but became much softer in its upper portion. An examination made, December 9, 1881, showed the tumor growing in all directions. It now projected into the pelvis behind the uterus, filling this part with a hard, nodulated mass; while above, as has been stated, it continued to soften as it ascended, giving it the feel of a cystic growth.

From this time it continued to grow rapidly, and by July, 1882, it was pressing against the liver and filling the whole abdomen, except the epigastric and left hypochondriac regions. Her general health was seriously impaired, and she had emaciated considerably. On examination I found the uterus displaced towards the right side: the sound entered five and one-quarter inches in the same direction. When in the uterus the sound did not follow closely the motions given to the tumor, while the tumor itself was found to be more fixed. The aneurismal vessel had enlarged considerably, and the thrill was much stronger.

Although I had dwelt upon and fully acquainted her with all the dangers of such an operation, yet she was very anxious to have the tumor removed, and as delay increased the danger, I proposed an exploratory operation with the understanding that if the tumor could not be taken away with ordinary safety, it should be left undisturbed, but in that case, if possible, the uterine appendages should be removed and the arteries in the broad ligaments tied.

The operation was performed November 2, 1882, in which I was assisted by Drs. W. P. Buck, W. S. Stewart, L. Harlow, of this city; Dr. I. Shellenberger, of Germantown; Dr. I. Eshelman, of San Francisco, and my son. An incision was made through the abdominal wall, midway between the umbilicus and pubis, of about three inches in length, down to the peritoneum, which was cautiously opened exposing a dark-red tumor with a rough surface. The structure of the tumor was soft, and it appeared highly vascular. Fearing to tear it, I passed my hand with extreme caution between it and the abdominal wall down towards the usual loca-

tion of the ovaries, but could not reach them. Great difficulty was experienced in doing this, owing mainly to the rigidity of the abdominal walls, which kept them in close apposition to the tumor, and it required the exertion of considerable force to separate them. While thus attempting to reach the ovaries I unfortunately tore a small opening in the upper surface of the tumor from which the blood flowed freely. It was found that this bleeding could only be controlled by pressure, for the structure of the growth resembled a sponge, and was so soft and easily torn that a ligature was worse than useless, as it would cut through the loose tissue leaving a larger bleeding surface. It being impossible then to arrest the bleeding by any other means than pressure, I was compelled to continue the operation for the removal of the tumor. To do this the incision was extended to three inches above the umbilicus, and downwards nearly to the pubis. The tumor was attached above and behind to the mesentery, while beneath it was adherent to the broad ligaments and ovaries which laid under it; these bodies having been displaced to such an extent downwards and backwards as to be completely out of reach until the tumor was raised. The pelvic portion was strongly adherent to the surrounding parts. The mass was removed from the abdomen with considerable difficulty, but when this was accomplished it was seen to spring directly from the fundus of the uterus by a broad pedicle. A large clamp was applied to this and the tumor cut away. The adhesions were soft and brittle, and tore readily, leaving a rough, coarsely granular, or spongy surface, and from every adherent point poured out blood. The main bleeding was from the adhesions around the brim of the pelvis and to the broad ligaments. The tissues about these adhesions were ragged, and the vessels difficult to secure, but I succeeded in arresting the hemorrhage. On raising the intestines, which had been thrust out by the contraction of the abdominal muscles, the torn mesenteric attachment was found to be bleeding freely. This surface required a great number of ligatures.

Immediately upon the withdrawal of the tumor from the abdomen, the patient became pulseless, the skin pale and moist, and in fact all the signs of intense shock presented themselves. This was before any serious hemorrhage had occurred. The active bleeding which immediately succeeded prevented any attempt at reaction, and although heat was applied, brandy given freely by the mouth as long as she could swallow, and hypodermic injections of brandy and morphia used, she sank and died just one hour after clamping the tumor.

This case is of great practical interest in view of the strenuous advocacy by many recent writers of the operation for the removal of the uterine appendages, as a comparatively safe method of arresting the growth of uterine fibroids. It proves that in these large fibromas such an operation is not only hazardous, but may be extremely difficult, and that, in fact, we cannot even be certain that we can reach these appendages, for in this case, so completely buried beneath the tumor were the ovaries and ligaments that neither could be found until it was raised from its bed, when they were discovered adhering to its lower portion. In an operation which I performed last winter the same difficulties were experienced: the ovaries could not be reached until the tumor, which was extremely large, weighing nearly a hundred pounds, was raised out of the abdomen. These, added to many other cases which I have met with, show that in large uterine tumors the removal of the uterine appendages may prove quite as dangerous as the extirpation of the growth itself, and be utterly impracticable unless the tumor is turned out from the abdomen. Now if this should have to be done in order to reach these bodies, which would of course necessitate the detachment of adhesions and risk a shock by the disturbance caused by raising the mass, it would undoubtedly be better practice to leave the uterine appendages untouched and remove the tumor itself.

This case teaches another practical fact, which I have not found alluded to by writers on this subject, that when we meet with the soft variety of these growths, the certainity of hemorrhage difficult to control is added to the other risks of the operation, and if the character of the tumor is recognized in time, and the presence of extensive adhesions determined, the safest plan for the operator to follow is to leave the tumor untouched, and close the wound.

DR. B. F. BAER (in response to a call from the Chair) inquired of Dr. Drysdale the effects of ammonium chloride and ergot as administered by him in this class of cases. Does not ergot, when given during the menstrual flow, increase the quantity of the discharge? Does ammonium chloride have any effect in reducing the size of the tumor? He had used ammonium chloride a great deal; in fact, he gives it in every case of uterine fibroid that comes under his care, but he has not seen or expected much from its employment. He considers it an alterative; it makes the patient feel better, but he has not seen any reduction in the size of the tumor follow its use: it relieves the painful flushings connected with the existence of a uterine fibroid or the menopause. He is not very sanguine as to the effects of ergot used in any way, hypodermically or otherwise, to reduce the size of a uterine tumor, and it certainly can effect nothing in the case of a pedicellated subperitoneal uterine fibroid.

As regards the hazard of the operation under the conditions existing in the case narrated by Dr. Drysdale, it cannot be too strongly expressed; but there have been instances of recovery under conditions apparently as desperate as those just detailed. The case referred to by Dr. Harris (chairman *pro tem.*) was operated upon by Dr. Goodell. The patient was a lady of middle age, who had been suffering from profuse hemorrhage which was endangering her life. This hemorrhage was the result of the existence of a large uterine tumor, and Dr. Goodell decided to attempt oöphorectomy as a means for her relief. An incision three or four inches in length was made in the middle line of the abdomen. The large size of the tumor made it very difficult to reach the ovaries. One was, however, reached and successfully ligated and removed without causing hemorrhage, although the pampiniform plexus was very much enlarged. It was necessary, in order to reach the other ovary, to enlarge the abdominal incision and roll the tumor over. It was found and removed, but a large plexus of veins was ruptured in the turning, and the hemorrhage was frightful—the blood escaping from both ends of the vessels; ligatures were passed through the substance of the tumor and finally succeeded in stopping the loss of blood. The Doctor thought he might be compelled to remove the entire uterus to stop the hemorrhage. This had happened to Knowsley Thornton.

This patient recovered, but Dr. Baer had seen death from peritonitis result in similar cases from the exploratory incision alone, the tumor and ovaries being found to be in so vascular a condition that Dr. Goodell was afraid to complete the operation.

DR. HARRIS remarked that he was present at this operation and was a close observer. The veins were ruptured during the turning of the tumor; there was a peculiar anastomasis of the large venous trunks at the point of rupture. In this case the tumor had formed no adhesions.

Dr. Harris had been present at an operation by Dr.

W. W. Keen in a similar case. The tumor was smaller but the hemorrhages had been so profuse before the operation as to leave the patient waxen in appearance. In this case the tubes were tied close to the uterus and were removed with the ovaries.

DR. BAER remarked that Dr. Goodell had been very successful in operating by removing the ovaries for the cure of metrorrhagia the consequence of uterine fibroids.

DR. GITHENS, in answer to the first query by Dr. Baer, remarked that although not successful in relieving menorrhagia by the internal use of ergot, he had had very satisfactory results from the use of ergotine suppositories in cases in which there was no tumor present.

DR. A. G. B. HINKLE alluded to several cases in which he had used ergot for the relief of menorrhagia due to the presence of uterine fibroids; he had given it three days before the period, during, and for three days after its close; he also gave ammonium chloride in ten grain doses, three times a day, all the time. This treatment had produced undoubted effects, and in some cases the tumors had disappeared.

DR. HENRY BEATES had used ammonium chloride in the treatment of a lady who had a large uterine tumor. He continued it one year with marked effect. The menopause came on two years afterward, and the tumor has now entirely disappeared.

Dr. Beates made some general remarks about the microscopical appearance in hard and soft uterine tumors, and thought that the effect of ergot would depend upon the presence or absence of muscular fibres as a component part of the tumor.

DR. DRYSDALE, in closing the discussion, urged upon the members the desirability of limiting the operation of the removal of the uterine appendages for the cure of uterine fibroids to small tumors, or to those in the early stage and which have not commenced to undergo the softening process. He had noticed, in cases under his care, a small spot of softening begin in a previously hard tumor and progress until the change was complete. The tumor presented this evening had undergone this change, and had undoubtedly assumed a malignant type. Before the operation it felt as if it contained a fluid; since its removal it has shrunk to about one-half its original size from drainage of blood. From the description given during the debate, the tumor in the case of Dr. Goodell differed from the one presented this evening, in being much smaller and free from adhesions. The hemorrhage in his case came from a single laceration in the tumor, and could be controlled. In this case, not only did the torn substance of the tumor bleed, but every detached adhesion poured out blood in abundance.

In reply to Dr. Baer's questions, he would say that ammonium chloride in some cases of hard uterine tumors is remarkably efficacious in reducing the size of the growths; he has repeatedly seen them entirely removed by the remedy. He had never known ergot to increase the loss of blood during the menstrual period, when used for the cure of intra-mural tumors; ergot has a decided effect upon the nutrition of these growths, but he would not expect it to act upon pedicellated growths, unless inside the cavity of the uterus.

DR. HENRY BEATES had been called in consultation to see a case of metrorrhagia. Ten years previously the patient had suffered from miscarriage at the fourth month. Subsequently each menstrual period became more and more profuse and prolonged, until at the time Dr. B. first saw her the loss of blood was constant and the patient was pallid and reduced almost to a skeleton, her weight being but ninety pounds. The curette had been previously applied to the endometrium, with the effect of increasing the discharge. Dr. Beates introduced a sound which passed to the left to a depth of five and a quarter inches; he introduced a laminaria tent of the largest size, and next day, by digital examination, discovered a sessile tumor; further dilation enabled him to remove the tumor by evulsion. It was necessary to divide it to deliver it through the os uteri. It was composed of fibrous and muscular tissue, and contained numerous dilated bloodvessels which had been the source of the hemorrhage before operation. Three years afterwards the patient's weight had increased to one hundred and fifty pounds.

DR. B. F. BAER read the following report of

A CASE OF LABOR WITH TWINS.

E. O., æt. 22, and single, entered Maternity Hospital on the morning of November 2, complaining of pains resembling those of the first stage of labor, although her gestation was computed to have reached only the beginning of the ninth month. These pains, she stated, began on the previous evening. Later in the day I saw her. Inspection of the abdomen showed it to be greatly distended and irregular in shape. By palpation I could readily outline, as I thought, more than one fœtus, and by auscultation I very distinctly heard the heart-sounds of two children—one high up and to the right, the other below the umbilicus and to the left. Twin pregnancy was diagnosticated. Vaginal touch revealed the os uteri to be dilated to about the size of a silver half-dollar, the lower segment of the uterus and cervix to be rather elongated than rounded, as in a presentation of the vertex. After some time spent in deliberation a presentation of the feet was diagnosticated. The pains were not strong, and they had very little effect on the cervix. The patient was in a fair condition, though somewhat excited. Her lower extremities were œdematous, her face a little puffy, and her urine contained a small quantity of albumen. The heart-sounds of the children were strong. I ordered fifteen grains of the hydrate of chloral and twenty grains of the bromide of potassium to be given at once. This dose was repeated once during the labor. Her bowels were moved by an enema.

Three hours afterwards the os was about double the size of that found at the first examination. The pains, still feebly acting on the presenting portion, had very little dilating power. As there was no special reason why the labor should be hurried, I waited two hours longer, at which time the feet were well down in the cavity of the pelvis, and projecting through the os, though the membranes were still unruptured. As the first stage of labor had now lasted twenty-four hours, and the patient was becoming tired, I felt that something more ought to be done to expedite the delivery; I therefore ruptured the membranes. One hour more was consumed before the feet reached the vulva. I now brought down the feet by extending the legs, and in a very short time after, without the least traction, the body followed as far as the shoulders, where it was arrested by extension of the arms. The arms were brought down as speedily as possible by carrying them forwards over the face. The child showed by its movements that it was still living, and the cord was feebly pulsating. The latter was relieved from pressure as much as possible. It was imperative that the head should be extracted speedily, or the child would die, but for some reason it would not descend. I at once recognized that the head was extended, with its long diameter in the conjugate of the superior strait, and that it was not yet fully freed from the grasp of the cervix, as the cause of the delay. I tried to flex the head and place it so that one of its antero-posterior diameters should correspond to the transverse of the superior strait, but could not, because, as I now recognized, the presenting portion of the second child was in the way. I could not reach high

enough to bring the proper force to ensure flexion of the head. I now very easily and quickly adjusted Simpson's forceps, when, by giving a slight oblique turn and carrying the handle of the instrument forwards, the head flexed and delivery followed almost immediately. Certainly, I think, not more than ten minutes elapsed from the time the body was expelled as far as the shoulders until the head was delivered. The child was alive but in an asthenic condition, and, although the usual efforts at resuscitation were applied, it died soon after.

Examination now revealed a presentation of the right shoulder of the second child, and that the presenting part was projecting through the superior strait. The membranes were unruptured. Version by the vertex was performed by the bimanual method, the uterus stimulated by friction and pressure on the fundus and the membranes ruptured. But the uterine contractions were very feeble, and it was some minutes before the head was secured from returning to its former position in the left iliac fossa, by having passed through the superior strait.

The uterus was now left to rest with the hope that it could spontaneously regain enough power to expel the remaining child; but after waiting nearly an hour, and finding that the head had advanced very little, a drachm of the fluid extract of ergot was administered *per orem*. This gradually spurred the uterus, and within thirty minutes afterwards the second child was born, or one hour and a half after the birth of the first. The uterus was so much exhausted that it was with difficulty made to contract by friction and pressure on the fundus, and it would relax again almost immediately afterwards. There was no evidence of separation of either placenta, in part or entire, because there was no hemorrhage. Therefore I concluded to let the organ rest for a time for the purpose of recuperation. I waited more than half an hour, of course not disregarding the liability to hemorrhage, open or concealed, and looking out for it. By this time the uterus was contracted pretty firmly around the placentæ, which were attached in the neighborhood of the right cornu. I now tried again, very thoroughly, to express them by the Credé method, but failed. Traction on the cords seeming to indicate that the placentæ were adherent, the only thing left to be done was the introduction of the hand. This I did with considerable difficulty. The uterus was firmly contracted at all points, except in the right upper portion, where it seemed to be paralyzed or prevented from contracting by the presence of the placentæ. This gave to the organ the so-called hour-glass shape. The placentæ were both adherent. I separated and withdrew them slowly, and held the emptied portion firmly by the external hand until contraction was secured. There was no further difficulty, and the patient left the hospital at the usual time.

I think the following points in the case of sufficient interest to warrant me in asking the Society's opinion on them:

1. The conduct of the first stage of labor. Ought I to have hurried it more, and thereby prevented exhaustion of the uterus? I think not. As it was, the os was not sufficiently dilated to allow the head to pass readily.

2. The delivery of the after-coming head. Placing the antero-posterior diameter of the child's head in the transverse diameter of the superior strait, and facilitating its passage, if necessary, by external pressure on the fundus of the uterus, the method so graphically described, and so earnestly and properly insisted upon by Prof. R. A. F. Penrose, as the proper plan of managing the head in ordinary breech presentations, was impracticable here, for the reason that the second child was in the way, both of placing the head transverse and of external pressure. Manual or forceps action on the head was the only resort. That I did not at once apply the forceps I am sorry, for delivery three minutes earlier might have saved the life of the child.

3. The choice of ergot in preference to the forceps as a means of facilitating the delivery of the second child. The administration of ergot for the purpose of expediting the delivery of the child cannot be too strongly condemned, as a broad rule, but that there may be an occasional exception I think must be admitted, and also, that this was one. The os and other soft parts were dilated by the passage of the first child; the pelvis was sufficiently capacious, the presentation and position normal. There was, therefore, no obstruction to the rapid passage of the child were the power furnished by the action of the ergot. Moreover, that the uterus was worn out, and wanted time and stimulation to recover, was proven by the history of the labor, as related. There would have been great danger of hemorrhage had the forceps been used to rapidly empty the uterus.

4. Morbid adhesions of the placentæ, causing irregular contraction of the uterus, or contraction of the organ in every portion, except opposite the attachment of the placentæ, where the contraction was not strong enough to separate them, giving the so-called hour-glass form to the uterus.

5. What influence had the ergot, if any, in inducing the irregular contraction? From my own experience, I would answer that I do not think it had any; first, because I almost always give ergot as soon as the child is expelled, and before delivery of the placenta; and, second, because I have never met with irregular contraction of the kind under discussion except in cases where the placenta was morbidly adherent.

The question, May ergot complicate the third stage of labor, by acting on the circular fibres of the uterus, at the internal os for instance, independently of the oblique and longitudinal fibres, incarcerating the placenta thereby? I should like to hear discussed. I take a negative view.

6. The presentations were unusual. The first child usually presents by the head, the second by the breech or feet. In this case the first presented by the feet, the second by the shoulder.

They were both males, and weighed conjointly twelve and a half pounds. The first child was the smaller of the two. This is unusual.

DR. HARRIS had had under his care a woman in labor with twins. The first one delivered was a female weighing eight pounds; it presented by the breech. After it came away the os uteri and soft parts contracted, and an examination made by one who did not know of the delivery of the first child, would not have discovered evidence of the fact but for the presence of the child. The bag of waters presented, and the os uteri was again dilated. Three and a half hours after the birth of the first child the second, a male, was delivered by the assistance of forceps; its weight was nine pounds.

DR. HORACE WILLIAMS related his experience in a case of twins. The first child descended in the fourth position and no rotation occurred, as it was held so by the second child; the pelvis was roomy, but laceration of the perineum resulted.

DR. B. F. BAER also reported the following

CASE OF UTERUS SUBSEPTUS, COMPLICATING THE THIRD STAGE OF LABOR.

Through the kindness of my friend, Dr. T. Stanton Crowley, I was permitted, on Nov. 29, 1882, to see the interesting case which I here briefly describe.

Mrs. M. G., æt. 24, was delivered two hours before I

saw her of her fifth child, after a rather tedious labor, in which the breech presented. The placenta was delivered with some difficulty about half an hour after the expulsion of the child; but the membranes were retained by what was supposed to be an hour-glass contraction of the uterus, or contraction of the internal os.

I found the uterus well contracted, but somewhat irregular in shape, as felt through the hypogastrium. The internal os was contracted closely around a portion of the amniotic sac, which was projecting through it. I gradually passed one finger and then two through the os, and found that the membranes were pressed upon and retained by a firm substance, which obstructed the passage. After still further dilating, I tried to pass my hand, or as much of it as was necessary to reach the membranes, which I traced to the left cornu. In doing so my thumb was directed to the right, by the obstruction above mentioned, and passed into another cavity, independent, apparently, of the one in which my fingers were. The latter cavity was comparatively large and contained the membranes. My first impression was that I was grasping a fibroid tumor which had been flattened by pressure, or possibly a supplementary placenta, which was detached and lying edgewise, but the result of further investigation proved that it was neither. I next removed the membranes—nearly the whole of the fœtal sac—and then made a more thorough examination. Again passing my hand partially into the uterus, whilst with the external hand I made counter-pressure on the fundus, my fingers entered a comparatively large cavity towards the left. This was rough—placental site—and cylindrical in shape. My thumb, as before, passed to the right and into another cylindrical cavity, small, compared to the left, and smooth. Grasping the septum which separated my thumb and fingers, I found that there was a complete division of the uterine cavity into two unequal parts. The septum was wedge-shaped, with the blade of the wedge below, ending at the internal os, and, therefore, not dividing the cervical cavity. Externally the organ was not perfectly symmetrical and smooth, but at the point opposite the septum a slight depression was felt.

This is the *uterus subseptus unicollis* of Küssmaul, or a uterus which is divided in the cavity of the body only, the septum stopping short at the internal os, not dividing the cervical cavity therefore. The slight sulcus on the external surface makes it approach the form described by the same author as the *uterus bicornis subseptus unicollis*.

I now became interested in the history of the former gestations and labors of our patient, and learned that this was her fourth labor and fifth child.

The first was a twin-pregnancy, and terminated in premature labor in the seventh month. There was an interval of more than an hour between the birth of the first and second child, and another interval of fifteen minutes between the expulsion of the placentæ. And they did not have even a membranous connection. Did each cavity have its own independent ovum, therefore? Not necessarily, but it is highly probable, because, as a rule, the placentæ of twins have a membranous connection at least, and in those uncommon cases where they are entirely separate, may not each fœtus have had its own independent chamber furnished by one of the forms of double uterus?

The second and third gestations went to term, but the labors were both complicated, requiring the aid of the forceps to supplement the imperfect expelling power of the uterus. We can readily understand why the uterine force was not applied to the best advantage on the fœtal ellipse in a case of this kind.

The fourth and last labor was complicated in its third stage in a manner which is new to me.

May not some other of the complications of the third stage of labor be due to an undetected malformation of the uterus, resulting from arrested development? For instance, the perfect hour-glass shape which a few observers are sure they have met with. The uterus bicornis subseptus, a form of malformation where the horns diverge, and where a septum extends into the cavity, dividing it into two, furnishes a case in which the finger would encounter a point of constriction before it could enter the cavity containing the placenta; and externally the hand would detect the apparent constriction at the bifurcation of the cornua. But you will answer that bicornate uterus is very rare. So is perfect hour-glass contraction of the uterus; and the malformation of the uterus might not be so rare as supposed if it were detected in every instance where it exists.

"Busch mentions a case of uterus bicornis septus, in which an exhausting hemorrhage occurred, in consequence of the attachment of the placenta to the septum, which, not contracting, the vessels remained open." (Klob.)

This malformation may account for some of the cases of super-fœtation, and menstruation during the early months of gestation. In this case the catamenia were absent during the whole of every gestation.

DR. R. G. CURTIN had this morning delivered a woman of twins; after the uterus was emptied and well-contracted, a strongly-marked sulcus could be felt in the fundus.

DR. DRYSDALE has under his care a woman whose uterus is divided by a complete septum.

DR. W. S. STEWART inquired if any previous examination indicated a want of symmetry, or if it resembled an extra-uterine pregnancy.

DR. BAER had not seen the patient until after the delivery of the child, and did not ask about the point mentioned by Dr. Stewart. Dr. Goodell has reported a case of supposed extra-uterine gestation in which labor came on naturally. This type of uterus may seem to be very rare because it is so difficult to recognize. The presence of the septum would never have been suspected in this case had it not been found in the attempt to remove the imprisoned placenta.

DR. HARRIS said that Dr. Goodell was uncertain of the character of the pregnancy, although every diagnostic test but one indicated that it was extra-uterine. This exceptional condition was the sensation of muscular contraction in the presumed cyst-wall when the hand was applied to the abdomen. Not being able to reconcile this action with the development of a tubal pregnancy, he determined to trust the case to nature, and sent the woman to the Preston Retreat, where she was delivered naturally in a few days. The uterus was double and was twisted on its axis, and the empty cornu was posterior, admitting the sound in the median line as into an empty organ.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, November 23, 1882.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

DILATATION AND ATHEROMA OF THE PULMONARY ARTERY, WITH AN OPENING THROUGH THE INTERVENTRICULAR SEPTUM.

Presented by DR. BRUEN.

Examination of the Heart.—Left side: Slight ventricular hypertrophy; mitral valves somewhat thickened at the margins, with roughening of their auricular aspect; valves competent; the left auricle is normal, as is also the aorta and the aortic valves. Examination of the right side is of most interest. (1) Two of the semilunar leaflets at the mouth of the pulmonary artery are nearly destroyed by atheromatous changes; the third segment

is much thickened, and projects as a leaf-like fold, roughening the mouth of the pulmonary artery. This vessel is dilated to nearly twice its normal size, forming really an aneurismal dilatation. The vessel's walls are covered with a fringe of vegetations of inflammatory origin, or due to atheromatous changes. The right auricle is very small and imperfectly developed, the bulk of its cavity being formed by the auricular appendix. The tricuspid valves are much thickened, but are competent, probably. Between the two ventricles is an orifice large enough to admit the forefinger; it is directly beneath one of the tricuspid leaflets, and is lined with endocardium, and must have allowed a free interchange between the blood of the two ventricles. The walls of the right ventricle are thinned, and its cavity somewhat dilated. Dr. Bruen said that this case was interesting because perforation of the ventricular septum is often congenital and dependent on obstruction of the orifice of the pulmonary artery, the perforation being due to the pressure of blood within the replete right ventricle. This pressure causes an arrest in the development of the ventricular septum. The pathology of the present case probably is as given above, but there was no pulmonary artery obstruction. A similar case is recorded in the *Medico-Chir. Trans.*, vol. xv., by Fletcher. (2) There was no cyanosis—cyanosis is usually dependent on a deficiency of cardiac evolution, or else on retarded evolution of the pulmonary artery or aorta. As a consequence, there is deficient cardiac power to carry on the circulation; or the pulmonary artery or aorta is narrower than normal, so that in any of these conditions venous repletion results and cyanosis. (3) Mixture of venous and arterial blood is the not usual cause of cyanosis, although it may be a factor. Walsh says, "Grant that perforations of the ventricular septum coexist with constriction of the pulmonary orifice, and cyanosis seems to become a certainty." In our case there is an example of incomplete development of the ventricular septum, and deficient development of the right auricle, without cyanosis. Pulmonary artery disease is consistent with a fair amount of general health; compensation by the right heart may occur just as in cases of aortic disease. (4) Descriptions of pulmonary artery disease call attention to bronchitis, pneumonia, hydrothorax, as sequential states. In our case, no such complications were present until just before death, when she finally succumbed to congestion of the lungs, added to the cardiac state. (5) The aneurism of the pulmonary artery formed a pulsating tumor on the left side of the sternum, between the second and fourth ribs, extending outward from the border of the sternum, and including an area covered by a trade dollar. (6) Over the solid tumor a post-diastolic and presystolic bruit-like murmur could be heard at a point between the second and fourth ribs; while close to their junction with the sternum a hoarse, systolic murmur could be heard. The bruit was localized. The heart systolic murmur was carried on into the entire arterial system. Dr. Bruen then detailed at length the differential diagnosis of these murmurs. During life, dilatation of the pulmonary artery with abnormal obstruction had been the diagnosis. The patient was a woman, æt. 26 years, a syphilitic, and was under observation from November, 1878, to July, 1882.

DR. ESKRIDGE had not had any difficulty in differentiating a presystolic from a diastolic murmur. He thought the leathery thickening of the mitral valves in the specimen presented by Dr. Bruen was sufficient to give rise to a mitral presystolic murmur. If we adopt the theory of Dr. Austin Flint, Sr., that a mitral presystolic murmur may occur in aortic regurgitation, when the mitral valves are perfectly healthy, it seemed to him that there was no difficulty in accounting for the presystolic murmur from the regurgitant blood from the pulmonary artery into the communicating right and left ventricles of this case, especially as thickening and loss of elasticity, with some rigidity of the mitral valves, existed.

DR. WILSON called attention to the evident relation between the incomplete ventricular septum and the condition of the pulmonary artery, which is greatly dilated and atheromatous and presents the appearances often met with in the aorta, very rarely in this vessel. The wall of the right heart is relatively thickened. This fact, together with the position of the opening in the interventricular wall which favors the flow of the blood from the left ventricle towards the pulmonary artery, renders it probable—almost certain—that the more forcible contraction of the left heart was constantly forcing a portion of its arterial blood into the right heart, thus increasing the current entering the pulmonary artery, and occasioning, first, hypertrophy of the right ventricle, and, second, a sub-acute inflammatory process in the pulmonary artery itself, in consequence of the increased volume and force of the blood-current. Dr. Shakespeare's observation that such growths as are here seen require for their existence arterial blood, is in accordance with this view.

SARCOMA OF THE PROSTATE GLAND,

Presented by DR. E. W. HUGHES.

The specimen which I have the pleasure of presenting to you this evening, was taken from a patient in the University Hospital under the care of DR. H. R. WHARTON.

W. E., aged thirty-five years, admitted to the University Hospital, suffering from retention of urine. Before his admission numerous unsuccessful attempts had been made to empty the bladder by means of a catheter. On admission the patient complained of much pain in the hypogastric region, which was the seat of a smooth, rounded swelling, reaching almost to the umbilicus. He stated that he had gonorrhœa some years previously, which had been prolonged into a troublesome stricture, which had been perfectly relieved by the passage of bougies. For more than a year previous to his admission he had suffered at regular intervals from difficulty in urination. The urine had never been bloody, but its passage had often been attended by great pain. It was found impossible, on account of numerous false passages, to introduce a catheter into the bladder. On introducing a finger into the rectum the prostate was felt smooth, rounded, and immensely enlarged. The patient was put to bed, ordered a suppository of belladonna and opium, and to have a warm poultice applied to the abdomen, this treatment relieving him almost immediately, and urination became freer. For a few days he did well, but the difficulty in urination soon began to increase, and by the fifth day after his admission the symptoms had become so urgent that it was deemed advisable to repeat the attempt to pass a catheter. This attempt was as futile as the first. Then aspiration of the bladder through the abdominal walls was attempted, but only a small quantity of blood was obtained.

In introducing the canula it gave the sensation of passing into a solid body, and careful palpation revealed the fact that there really was a solid body apparently occupying the whole bladder. It was now decided to open the urethra at the base of the bladder through the perineum, and the operation known as Cock's was selected. The operation was followed by the escape of a small amount of urine. After this, the patient did well, with the exception of an attack of dysentery, until the ninth day after the operation, when peritonitis suddenly developed. He died on the following day.

Autopsy (two hours after death).—Upon opening the abdomen, a thick yellowish-red purulent liquid, having a urinous odor, was found bathing the intestines, the walls of which were everywhere bound together by recent adhesions. The omentum was in places firmly adherent to the intestines, and contained numerous irregular nodular masses, varying in size from that of a pea to that of a hen's egg. These masses on section presented a violet-yellow color. In the lower part of the abdominal cavity was a large irregularly-shaped mass, firmly adherent to the small intestines, colon, omentum, and walls of the pelvis. On careful dissection a tumor was found to originate in the prostate gland. On section it presented in parts the characteristics of scirrhus, in others those of encephaloid; in other places there were loculi, with reddened irregular friable walls filled with a fluid similar to that found in the abdominal cavity, though no connection between these loculi and the abdominal cavity could be found. No trace of normal prostate gland nor seminal vesicles could be discovered. The bladder, containing a few ounces of urine, was found in front of the upper portion of the growth, its upper boundary almost on a line with the umbilicus. Its anterior wall was apparently perfectly normal; its posterior wall, resting on the tumor, was thickened, raised, red, and velvety. The ureters were normal and opened in the usual position. The urethra, as far as could be seen, ran along the anterior surface of the tumor, and was not involved by it. The weight of the growth was five pounds two ounces. The kidneys, stomach, lungs, and intestines were normal. The peritoneum and capsules of the liver and spleen contained several secondary growths. The brain was not examined. Microscopic examination showed the growth to be a typical small round-celled sarcoma. The secondary deposits were similar in structure to the primary growth. The submucous and muscular tissues of the bladder walls were somewhat infiltrated. The growths in the capsules of the liver and spleen had commenced to penetrate those organs.

MELANOTIC SARCOMA OF ORBIT, WITH METASTASIS TO LIVER, ETC.

Presented by DR. SHAKESPEARE.

The patient was an elderly woman who had been operated upon by Dr. Heyl at the Episcopal Hospital some six months before death; the whole contents of the orbit having been then thoroughly removed. Recurrence took place, the cavity being filled with a black fungating mass; the left nostril gave vent to a blackish discharge, and the various internal organs became involved, notably the liver. Death took place from exhaustion. Most of the metastases were entirely melanotic, but some in the liver showed at their periphery a distinct whitish zone. Dr. Shakespeare remarked upon the singular fact that orbital growths were usually melanotic, although they might not spring from the choroid coat of the eye as in this case, where all pigmented structures had been removed months ago.

CORRESPONDENCE.

THE NON-IDENTITY OF CROUP AND DIPHTHERIA.

To the Editor of THE MEDICAL NEWS.

SIR: In reply to Dr. MacGillvary's letter in your issue of November 11, I can only repeat with Locke, "Let us define our terms." The whole dispute concerning diphtheria and croup arises from looseness and ambiguity of expression. The word "croup" is used very vaguely by the lay public, and even by a majority of the medical profession. Three distinct diseases are in fact covered by the term in its popular meaning, viz., (*a*) catarrhal laryngitis, (*b*) laryngismus stridulus, and (*c*) membranous inflammation of the larynx, which is, in my opinion, identical with diphtheria. Dr. MacGillvary appears to rest his view of the duality of the diseased condition on the presence of an infective property in diphtheria which he supposes to be wanting in croup. If false membrane is confined to the small area of a child's larynx, there is undoubtedly less chance of the disease being transmitted than when the much larger surface of the pharynx is covered with the *materies morbi*. It is, however, extremely rare to meet with a case in which the larynx alone is the seat of the disease. When, on a recent occasion, circulars relating to this question were addressed by the Medico-Chirurgical Society of London to members of the profession throughout this country during the many months the committee was sitting, not a single patient could be discovered who was suffering from false membrane limited to the larynx. To this I may add that during my own experience, which extends over five and twenty years, I have never met with such an instance, and I believe that when practitioners have imagined that they had to deal with membranous laryngitis the cases have in reality been examples of acute catarrh without exudation. The tendency to spasmodic affections in children, so familiar to every practical physician, is shown in the larynx, even where there is no congestion of its lining membrane. If inflammation occurs, spasm is almost certain to supervene, and this symptom is brought into great prominence, owing to the extreme narrowness of the glottis in young subjects, even in its natural condition.

It is obvious, therefore, that mistakes in diagnosis, involving the very essence of the affection, may easily be made. Your obedient servant,

MORELL MACKENZIE.

HARLEY ST., LONDON, Nov. 30.

THE NEW YORK CODE.

To the Editor of THE MEDICAL NEWS.

SIR: In your brief comments upon my note to the *Louisville Medical News*, touching the existing New York Code of Medical Ethics, you quote from the editorial comments of that journal as follows: "We imagine the thoughtful reader will find no little difficulty in following Dr. Agnew through the premises which seem to have led him to the conclusion that to protect the public from quackery the medical profession should take the quacks into fellowship and thus publicly recognize them as physicians worthy of confidence and affiliation." It will take the intended sting out of the comment if I simply say that I have nowhere said anything that might fairly, even with the exercise of the imagination referred to, be construed into any such proposition. The existing Code in my State contains the following clauses: "Members of the Medical Society of the State of New York and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity." Now, you will observe, that the first clause is permissive, not mandatory, and any member of the State society, or of affiliated societies, may avail himself of the liberty accorded or not, as he chooses, and its operation is confined to *legally* qualified doctors. The second, or emergency clause, as it has been called, simply authorizes a practitioner to answer any call, regardless of whom he may come in contact with, regardless for the moment of the character, even, of that person, and bent only on doing a humane act. It is, of course, inferred that a member of a learned profes-

sion is sufficiently familiar with English to know the meaning of the word "emergencies." Nowhere is it proposed to take quacks into "fellowship." Fellowship means "companionship," "association," "confederacy," "communion," "intimate familiarity."

A legally qualified practitioner may, it is true, be a quack, if we adhere in strictness of definition to the accepted etymology of that word, but not one in the eyes of the law. A quack by nature is a "boaster," a "bouncer," a "noisy, ostentatious talker," as when a man parades his virtue and decries that of other men; a pretender to medical skill, "quacking, ducklike, about his cures," "an ignorant practitioner," an "empiric."

In the State of New York the statutes are such that if any man should apply the opprobrious term of "quack" to a man possessed of a diploma duly obtained from an authorized college, he might be made to smart in exemplary damages for it, even though the person so characterized were a "homœopathist" or an "eclectic."

The writer in the Louisville journal goes on to say that "the great principles of ethics and morals are immutable, and are altered neither by longitude nor latitude," etc. I suppose that we may take it for granted that no one will deny the idea of the principle of abstract right and wrong, which the writer probably intends to assert. The only real test, after all, in morals, is "What saith the Lord?" and we cannot get away from the correlative fact that "Where the spirit of the Lord is, there is liberty." I would like to know what violation of *good morals* there would be in my meeting in consultation, for a beneficent purpose, in the State of New York, a man pronounced by the authority of the State to be a "*legally qualified practitioner.*" We must bring the matter down to some such simple test. I am not compelled to meet any one in consultation. I may, for reasons personal to myself, refuse to meet the very embodiment of all the native qualities of Hippocrates, but I will, at my peril, refuse to meet a "legally qualified practitioner," if I couple with my declination, the assertion that he is a quack. Such a person suing me for libel in the courts of the State of New York would easily get exemplary damages; indeed, such decisions have been made, and I am glad of it, as it marks a step of progress from barbarism and mob law, and in the direction of teaching men to bridle their tongues. Things are said in medical journals, and elsewhere, in apparently safe retreats, which the writers would not dare to utter in the presence of the individuals at whom the acrimonious utterances are directly or indirectly aimed, or in the presence of an officer of the law.

You say also, "Dr. Agnew unfortunately fails to point out how the new Code is going to influence these reforms," etc., etc. I have repeatedly endeavored to show how it may do so, but especially by displacing the old Code, and no one is more conscious than myself of the imperfection of my attempt, or of the general feebleness of my advocacy. Fortunately, however, a good cause has germinal qualities of its own, which cannot often be roasted out of it by the heat of controversy, or blasted by the insufficiency of its adherents and advocates. So long as we attempt to defend the public against quackery by mere proscriptive codes of our own professional making, we are attempting, as it were, to put out a fire with a garden syringe. Every one knows that the old Code had lost its punitive power with the very growth of society, advance of legislation, and practical ethics. In attempting to assert this I laid myself open to the strictures of my *Louisville Medical News*' critic. When the State undertook to express, in the form of statutes, as in my State in the statute of 1880, what a legally qualified practitioner was, that moment all definitions in our old Code as to what a legal doctor was, which conflicted with the statute, became inoperative and cumbersome, if not ridiculous.

It is a great step in the right direction to have the State assume the responsibility of determining who a legally qualified doctor is. Now, what are we to do in the State of New York? Practise under the law, and by experience of its workings learn to make it better. Enforce the law as it is, and have it amended whenever defects are discovered.

This course is being pursued with more or less success now, not only in New York, but in over twenty States and Territories of the United States. Nearly two thousand medical tramps have been driven out of Illinois alone, by the operation of its registry law. The paragraph on page 699 in your issue of the 16th, shows what we are doing in New York.

We intend to make it too hot here for quacks and outlaws, and trust that after Pennsylvania sees how well the law works your journal may advocate the enactment of a similar law, or a better one. We cannot, in our State, have the *imperium in imperio* certain to result if the State Society which derives its life and authority from the State is practically in opposition to the State. Especially is this so when the latter goes as far as public opinion has demanded in fixing the legal qualifications for practising medicine. We must, with the whole body of legally qualified doctors, sustain the State law and cultivate public opinion as rapidly as possible to make the law better and better. We will give great aid, moreover, by pushing on reforms in medical education, and supplying from our medical schools a better type of doctors as instructors of the people. We wish to encourage, in every way, rivalry between the States in perfecting laws against quacks till we reach a point where a quack will become a mere tramp. Results thought by many to be as utopian have been accomplished. We need, at the same time, each man for himself to examine his own conscience to see how far he may be, at heart or in acts, more or less a quack. Do we never boast or talk ostentatiously about ourselves and decry our medical neighbors? Do we never in medical journals or elsewhere pretend to have virtue and skill which we do not really possess? Let us remember the fable of Valentine and Orson. Let us hold up in our own lives the "burnished shield" of evidence and conquer our brother by the reflection of his imperfections. If we self-called regulars were ourselves less marred by the blemishes we see in quacks, we perhaps might do more good in leading legislators to embody true reform, and high ideals, in better laws for the public good.

Yours faithfully,

C. R. Agnew.

New York, December 17, 1882.

OBITUARY.

JOHN FORSYTH MEIGS, M.D.

Dr. Meigs died in this city on Saturday, December 16th. By his death Philadelphia has lost one of her most eminent physicians and upright men. It is a great loss. Even in so large a community as this no one is so high or so pure as not to have been strengthened and encouraged by the example of such a life as his.

Dr. Meigs was a son of the late eminent professor of obstetrics, Dr. Charles D. Meigs, who gladly took advantage of the disposition to study medicine which this one alone of all his sons exhibited. Perhaps, afraid that he might, as he grew older, find stronger attractions in a different field, his father placed him as a mere boy in the medical department of the University of Pennsylvania. The writer of these lines well re-

members his more than boyish appearance on the benches of the lecture-room, and his grave and absorbed expression while listening to the eminent teachers who filled the chairs of the school from 1834 to 1838, the year of his graduation, when he was but twenty years of age. It always appeared to the writer a serious error, the commission of which, by a man of such varied learning and elegant tastes as the elder Meigs, was difficult of explanation. A powerful motive must have determined him to urge his young son to enter upon the most difficult, because the most exhaustive, of professional studies, without either the maturity of mind, or the liberal education which fitted him for the investigation of medical subjects. Possibly, probably even, it was the father's anxiety that the beginning of his son's career should be guided and supported by himself, which caused him to burden so immature a youth with the grave and difficult matters that abound in medicine.

Fortunately, the son was very unlike the students who surrounded him, and from whom he kept almost entirely aloof, devoting himself with serious assiduity to his medical studies.

In this narrow and perhaps tedious road he betrayed no weariness or impatience, for he had not inherited the impulsive ardor or the sensitive genius of his distinguished father, but delighted, rather, in steadily hewing his way forward through all the obstacles that opposed him.

Immediately after graduating in medicine he was elected a resident physician of the Pennsylvania Hospital, and there the writer, who had been studying abroad, first knew him personally and as a colleague. For a year these two young men occupied the same room in the hospital, and formed a friendship that never failed until it was broken by death. The frank, simple, and steadfast character of young Meigs inspired his companion with affection for him; and his zeal in gaining knowledge, and his devotion to his duties, were then as conspicuous as they continued to be throughout his professional career of more than forty years. On quitting the hospital, he spent more than a year abroad, paying, indeed, some attention to medicine, but still more to the interesting objects of an European tour.

On his return he at once began the practice of his profession under the eye of his father, who gave more or less into his charge the younger members of the numerous families he attended. He entered zealously into the work, not as a mere practitioner, but also as an observer of disease, recording minutely the history of every case, so that in the course of a few years he accumulated a large mass of material which formed the basis of his lectures and of his work on the "Diseases of Children." This treatise established his reputation in connection with the department of medicine to which it belongs, and was at first, as it still continues to be in its seventh edition, the best work upon the subject in the English language. By degrees his practice, no longer confined to persons of tender age, embraced the older members of the families who had received innumerable proofs of his conscientious and unsparing devotion and his remarkable practical tact and skill, and then expanded beyond this personal limit, until both time and strength failed him to respond to all the demands upon his services, which were also constantly required in consultation.

On several occasions the health of Dr. Meigs suffered under this excessive strain, and obliged him to suspend his active labors. Again and again he was warned against so lavish an expenditure of his powers, but no warning or persuasion availed permanently, or in any great degree, to lessen materially his professional ardor and industry. His work had always been the passion of his life, and his death by devotion to it became a martyrdom.

The most important public office held by Dr. Meigs was that of attending physician to the Pennsylvania Hospital. He performed its duties for twenty five years with great devotion and enthusiasm. He perhaps cherished them above all other professional occupations, and took especial pains with his clinical lectures, which were as remarkable for the personality that pervaded them as for the soundness of the practical lessons in which they abounded. A number of them which were published from time to time are distinguished by these characteristics.

In earlier life he was one of a corps of lecturers known as the "Philadelphia Association for Medical Instruction," in which he at first gave several courses of lectures upon the diseases of children, and afterwards upon "Practice of Medicine." These lectures were the original and formal foundation of his published treatise already mentioned. He also produced a number of occasional papers, among which may be mentioned those relating to the "Blood in Malarial Diseases;" "Coarctation of the Aorta;" "The Use of Cold Water;" a "History of the Pennsylvania Hospital," and a "Life of Dr. Charles D. Meigs." The last of these was prepared for the College of Physicians.

The fatal illness of Dr. Meigs was due to a pleuropneumonia, involving originally the left lung, but soon extending to the right also. It terminated his life on the sixth day of his confinement to bed.

The sadness inspired by the death of Dr. Meigs is not mitigated by the knowledge that he has fallen a victim to that peculiarly American habit of life in which a maximum of labor is associated with a minimum of recreation, and whose object is too often attained when the capacity of enjoying it is exhausted. A life more evenly balanced by pleasure and toil would certainly have been a happier one to our lost friend, and probably would not have been so abruptly and prematurely ended.

SIR THOMAS WATSON, BART., M.D.

A cablegram of December 12th, announces the death, in London, of Sir Thomas Watson, Bart., M.D., Physician in Ordinary to the Queen. He had reached so advanced an age, and had so long ceased to appear in print, that those who remember Watson as the author of a text-book on practice with which they were introduced to the subject, may experience a feeling of surprise that he has lived up to the present time. He was born in 1792, and was educated at Cambridge, where he took his B.A. as tenth wrangler in January, 1815. He was 27 years of age when he began the study of medicine at St. Bartholomew's, and became M.D. in 1825. He was first appointed to the Middlesex Hospital, and afterwards to King's, where he delivered the course of lectures which made him famous when published in the *Medical Gazette* in 1844. These lectures, known as "Watson's Practice," became at once immensely popular. Their simplicity and elegance of diction, the scholarship without pedantry, displayed, and the admirable clinical skill which characterized them, were the distinctive features which rendered them a universal favorite. Besides the numerous editions in England, there were a great many reprints in this country. The great excellence of Watson's Practice was not the sole cause of its popularity; it must be remembered that at that time there were few candidates for professional favor in this department of medical knowledge. However, no amount of competition in the same field would have prevented the success of such a work. In 1859 Dr. Watson was appointed extraordinary physician to the Queen; in 1862 he became

D.C.L. of Oxford, and LL.D. of Cambridge. He had now reached the position of the leading consultant in London, and was called on in the fatal illnesses of the Princess Mary, the Duke of Cambridge, and the Prince Consort. Subsequently he became the physician in ordinary to the Queen, and was created a baronet. Until a very recent period he continued in active practice, and for many years was the most trusted medical adviser of the higher classes of English society. In the photograph which accompanies the sketch of Dr. Watson's life, published in the "Photographs of Eminent Medical Men of all Countries," issued by Churchill in 1867, we see a countenance of mingled benignity and firmness. He is seated in his library, surrounded by his books. His neat attire, the associations of a cultured physician, and the thoughtful countenance, make up a most interesting *ensemble*, and reveal, at the same time, the literary character and professional eminence. Such was the position of Watson in London —scholar, gentleman, and physician—a scion of an old family, a wrangler of Cambridge University, and the leading practitioner of the metropolitan city of England.

NEWS ITEMS.

NEW YORK.

(*From our Special Correspondent.*)

NEPHRECTOMY.—The operation of nephrectomy, so popular of late in New York, has not been resorted to as enthusiastically as it was before the recent removal of the kidney from a patient in one of the city hospitals. No urine was passed after the operation, and the woman died in two days. It was found that there had been but one kidney—that removed by the surgeon.

THE NEUROLOGICAL AND MEDICO-LEGAL SOCIETIES, long noted for internal wars, have lately been figuring in the daily papers. Two rival nominees for the Presidency, Dr. W. A. Hammond and Mr. Claude Bell, have had an exciting contest. Mr. Bell, however, defeated his opponent after a hot fight, and both parties smoothed their ruffled plumage at a handsome supper given at the Brunswick Hotel subsequently by the successful candidate.

CHANGES IN THE POST-GRADUATE MEDICAL SCHOOL are in order: Dr. M. A. Pallen has resigned to go to London, his place to be filled by Dr. B. W. Dawson, formerly editor of the *American Journal of Obstetrics*. Dr. H. G. Piffard has also withdrawn from the faculty.

BROOKLYN.

(*From our Special Correspondent.*)

ISOLATION OF INFECTIOUS DISEASES.—At the King's County Hospital there has long been a need for accommodations suitable for the treatment of infectious diseases. The supervisors have been very slow to recognize this want, although it has been repeatedly brought to their attention. That they are awaking to its importance, is shown by the following paragraph taken from a recent report of their committee on hospitals:

"While there are evidences of good management at the hospital, some additional facilities are very much needed. Those now at the disposal of the superintendent are so limited that he finds himself unable to classify certain patients who never should be allowed to be near each other. That is to say, diphtheitic patients are now consigned to the same ward in which fever patients are kept for treatment, the same practice being necessary so far as those suffering from other contagious diseases are concerned. It is scarcely necessary to say that a patient suffering from one infectious disorder is by no means insured of immunity from another, so that to mix these classes of inmates is to subject them to a danger which might easily be avoided at very small cost."

The light spreads slowly, but it spreads.

SANITARY CONDITION OF SCHOOL BUILDINGS.—There has been a systematic survey made of the sanitary condition of all the private schools of the city, especially in respect of their drainage and plumbing. In not a few instances, serious defects have been found by the inspectors, and the health of the pupils has been thereby impaired.

THE NEW HOSPITAL BUILDING OF THE ST. MARY'S HOSPITAL was formally opened Sunday, December 17, and was attended by hundreds. Visitors coursed through the finished wing from 11 o'clock till 5. At 3 o'clock, those who gained access to the hall were addressed by Bishop Loughlin and Mayor Low. The hospital is admirably arranged and will be under the charge of the Sisters of Charity. Dr. John Byrne has borne the brunt of the labor of progressing this institution, giving it thought, time, and money. He has associated with him a large medical staff, divided into specialties, not simply those peculiar to a hospital for women and children such as was the old basis of St. Mary's, but also those that frequently have their own separate institutions, such as the specialties of the eye and ear, the skin, the nervous system, and the joints. It is claimed that this is a new departure, never before developed in this or any other country.

BOSTON.

(*From Our Special Correspondent.*)

DR. CARPENTER ON HUMAN AUTOMATISM.—In opening his *third lecture* upon human automatism, Dr. Carpenter said that the subject of the evening (the automatism of habit) was one upon which metaphysics unaided by physiology have been unable to cast any light. For example: Stewart, a metaphysician of great merit, thought the act of walking to be always voluntary. Other metaphysicians considered it needful to suppose an infinitesimal amount of volition, which practically is no volition at all, and thus corresponds to the theory of physiologists. As already shown, the ordinary movements of the lower animals originate in a mechanism native to the animal itself. A further proof of this fact is found in the movements of a frog whose cerebrum has been removed. Effect this by decapitation, and the frog will still assume its ordinary position of repose. Prick its foot, and it will jump; apply acid, and the foot will be raised in an attempt to wipe it; cut off this foot, and the other will begin to act. More remarkable is the result when the cerebrum has been removed without disturbing the ganglionic tract, a continuation of the axial line, corresponding to the anterior portion of the nerve-cord of a centipede, and which in the human body the lecturer has always considered the primary recipient of impressions made upon the senses—sight, hearing, etc.

The frog, when thus mutilated, will originate no movement unless touched or otherwise disturbed. When touched, however, it will jump, and will so direct its spring as to avoid an obstacle, which, (the optic ganglion being intact) evidently is seen not precisely by the frog, which is unconscious, but by the ganglion which consequently directs the motor functions of the connected ganglia. Under like conditions, the frog, if stroked will croak in a peculiar manner and, placed

upon the hand, the latter being gently inclined, will climb to a position of security. These movements all find a parallel in the actions of human beings when the cerebrum is either quite passive, as in sleep or coma, or else is being used in other directions, the chief difference being that while in the frog all motions necessary to life are provided for by innate mechanism, in *us* the mechanism for many motions has to be shaped by the original operation of the will.

Dr. Carpenter expressed the belief that the axial cord with its sensory and motor nerves is *wholly distinct from the cerebrum*, and that the latter receives information of what the cord is doing through the ganglionic line already mentioned, and gives its orders through the same medium. Strong corroboration of this theory lies in the fact that paralysis follows a lesion, not of the cerebrum, but of this ganglionic tract. Distinct pathological proof of independent action of portions of the axial cord has been supplied by cases of accidental division of it. Dr. William Burke, of Bristol, records the case of a man whose axial cord was divided by an injury to the spine in the small of the back above the ganglionic centres which control movements of the legs. The man was entirely unable voluntarily to move his legs and quite unconscious of anything that was done to them, yet if the soles were tickled or a hot plate applied, the legs moved at once without the man's knowledge. The testimony of military men who have seen nearly entire regiments walking when sound asleep, and numerous instances of men riding on horseback in the same state, prove that when once established, these acts require no further direction from the will. Yet, the operation of walking calls into action nearly every muscle in the body and requires a process of balancing so complex that hitherto it has been impossible to construct a walking automaton. The explanation of these automatic movements is that the will has so directed nutrition to certain portions of the nervous system that these have shaped themselves into automata capable of performing their several motions whenever they are so excited by the will.

Cases of perfect insensibility, or coma, resulting from apoplexy have often occurred with similar effects. A London policeman in this condition continually caressed and adjusted his moustache, of which in his conscious state he was very proud, and which he was in the habit of manipulating in this manner. A rope-maker in a state of coma, began to twist a cord whenever it was placed between his fingers. Sundry other examples were given. In India the punkah pullers continue their work when asleep as perfectly as when awake. But in their case heredity has entered the problem, through the system of caste, the same families having followed the occupation for centuries.

A good instance of this creation of organic mechanism by direction of the will is the process of speech. Articulation, as well as the production of musical tones, is guided by the sense of hearing. Deaf mutes never learn to articulate by themselves, and when taught they learn by attention to the muscular sense of the motions of the vocal organs. In a case of total deafness the result of an accident at nine years of age (Dr. Kitto), the use of the vocal organs became disagreeable, and they were abandoned until friends urged assumption of their use.

Dr. K. explained that he gave up speech because he was obliged to guide the vocal organs by the unaccustomed process of attention to the muscular sense, which wearied him just as it fatigues one to roll the eyes in a perfectly dark room, where the movement requires attention to the muscular sense, instead of being automatically guided by ganglia under the influence of light. In training a deaf mute, the first step is to place his finger on the teacher's larynx, so that he may feel the vibration caused by formation of tone. His finger is then placed on his own larynx, and he is encouraged to create a similar vibration. This reproduction, by repetition, becomes the basis of automatism of vocalization, and the process is a model for the formation of all secondary automatic motions. We train our automata in the acts of writing, drawing, in instrumental music, etc., and when automatism is once established the cerebrum says to the spinal cord: "Do this," and the cord does it for us—not by us. Thus a pianist will play difficult music when the mind is engrossed by something else. A lady in Dublin once played dance music an entire evening while asleep, it being necessary only to awaken her sufficiently from time to time to make her understand what movement, waltz, quadrille, etc., was wanted; telegraph clerks sometimes despatch messages while asleep, or thinking of other matters. One testifies that he can read the message and put it into the movements necessary to the machine while asleep, with less liability to error than if he gave his attention to the process. Morbid phenomena confirm the theory.

In tetanus the ganglionic tract in the head is not much affected, fixation of the respiratory muscles being the chief cause of death; but in hydrophobia, an allied disease, convulsions are caused by the sound or sight of water, by a picture of it, stranger still by suggestion of it, thus corroborating the former statement that equal effects are produced by exciting the ends of nerves and by impulses from the brain. Yawning is another illustration; ordinarily it is owing to the accumulation of carbonic acid in the lungs, the result of practically suspended respiration due to fixation of the attention. The carbonic acid irritates the terminal ends of the nerves, and the reflex action of gaping follows. The sight of yawning in others will also induce a yawn, in this instance the result of brain impulse. The necessary condition in all these instances is that the nerve centres must be predisposed to a particular act, which may then be caused either by a stimulation of the nerves or by an impulse from the cerebrum.

CANADA.

(*From our Special Correspondent.*)

TROUBLE IN THE MIXED MEDICAL CLASS AT KINGSTON.—Trouble has arisen at the Kingston Medical School between the male and female students. The latter took offence at a remark made by the Professor of Physiology, and left the lecture-room. The male students petitioned the faculty to dismiss the ladies, and threatened to leave in a body if their request was not complied with. The faculty refused to be dictated to, and it was subsequently arranged that the females now attending will be allowed to finish their course, but no more of the sex will be admitted to the college.

NOMINATIONS.—The President sent the following nominations to the Senate last Friday: Colonel Robert Murray, surgeon, to be colonel and assistant surgeon-general; Lieutenant-colonel John F. Hammond, surgeon, to be colonel and surgeon; Major Basil Norris, surgeon, to be lieutenant-colonel and surgeon; Captain Frank Macham and Daniel G. Caldwell, assistant surgeons, to be majors and surgeons.

A CASE OF LEPROSY IN MASSACHUSETTS.—A case believed to be genuine leprosy has developed in the almshouse at Salem. The patient is Charles Derby, who arrived there from San Francisco a week ago. The disease is pronounced leprosy by a sea captain and a physician who was familiar with that disorder in Africa. A consultation of six leading physicians has been held, but they arrived at no decision, and Dr. Walcott, of the State Board of Health, passed his judgment on Decem-

ber 18, that the case was unquestionably leprosy, and that the disease was contracted in the Sandwich Islands. Derby is well educated, and was for some years at Honolulu as chief botanist to Queen Emma. He has been isolated and his clothing burned.

A LEGALIZED EDUCATIONAL FRAUD.—Charles J. Eastman, Rufus K. Noyes, and W. D. Corken, corporators and officers of the Bellevue Medical College, recently arrested on the charge of issuing bogus diplomas, were examined before Commissioner Hallett on December 15, at Boston, on charges of using the mails for fraudulent purposes. Evidence was offered by the Government, and was not contradicted, to the effect that the college had issued degrees and diplomas to individuals grossly ignorant of the theory and practice of medicine, and after a farcial course of instruction covering a few weeks or less. Defendants claimed simply that they were empowered to do all that was alleged, by the laws of Massachusetts. It appeared that the institution was legally incorporated, and that, according to the corporation laws and its charter, it enjoys all the privileges of other medical colleges. These facts were admitted by the Government attorney. Commissioner Hallett said if the Faculty chose to issue degrees to incompetent persons, the laws of Massachusetts do not prevent them. The prisoners were therefore discharged.

PROF. VIRCHOW'S HEALTH.—PROF. VIRCHOW'S health is slowly but steadily improving; he is now driven every day in a closed carriage to the Pathological Institute, but avoids all work which requires him to be out of doors.

A DIRECTORY FOR NURSES IN SAN FRANCISCO.—A directory of nurses will be opened in San Francisco, under the direction of Dr. A. S. Whitwell.

IMMIGRANT INTRODUCTION OF SMALLPOX INTO THE UNITED STATES.—Dr. John H. Rauch, Secretary Illinois State Board of Health, states that in reviewing the experience of the past six months' operations of the Immigrant Inspection Service, in connection with the history of smallpox in Chicago for thirty-two years, and the testimony of leading health officials concerning the origin and spread of the epidemic of 1880–82 in the United States, the truth of the following propositions seems to him to be demonstrated:

1. The immigrant is a prime factor in the origin and continuance of smallpox in the United States—on the one hand, even if protected himself, often being the bearer of the contagion in clothing and other effects; and on the other, if unprotected, frequently becoming a victim to the disease and propagating it to others.

2. Local effort and expenditure, either by State or municipalities, are inadequate to the control of smallpox in any given community or commonwealth, so long as the contagion and the material for the propagation of the contagion continue to be replenished by repeated accessions of unprotected or imperfectly protected immigrants.

3. A continuous sanitary surveillance of immigrant travel, from the port of arrival to the point of ultimate destination—such surveillance to consist of repeated inspections, vaccination of all unprotected, systematic observation of suspicious sickness, prompt removal and isolation of discovered smallpox or other contagious cases, disinfection of baggage, clothing, cars, etc.—is essential to supplement whatever preventive measures can be secured before embarkation, during the voyage, or at the port of arrival.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending December 9, 1882, indicate that intermittent fever, influenza, tonsillitis, and pneumonia, have increased; that neuralgia, diphtheria, and typhoid fever, have considerably decreased, and that typho-malarial fever, bronchitis, cholera morbus, diarrhœa, and whooping-cough, have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria and scarlet fever were reported present during the week ending December 9th and since, at 16 places, and measles at four places, smallpox was not reported at any place in Michigan.

OBITUARY RECORD.—Died at Brooklyn, New Yoak, December 12th, DANIEL ALBERT DODGE, M.D., in the 54th year of his age. Dr. Dodge was an eminent and skilful surgeon, a most genial gentleman and well beloved by his collaborators. He was for more than twenty years a member of the surgical staff of the Long Island College Hospital, of which institution he was a visiting surgeon at the time of his demise. He was an untiring and faithful practitioner, notwithstanding his health was frail for many years. He was the subject of chronic valvular disease, supervening in a fatal attack lasting over a month, of cerebral embolism. He was an alumnus of the College of Physicians and Surgeons, New York, of the class of 1852.

NOTES AND QUERIES.

THE NEW YORK CODE.

To the Editor of THE MEDICAL NEWS.

Sir: I fear that some of the readers of your journal will get the impression that the last meeting of the Medical Society of the State of New York was made up of delegates and members who were coached to sustain the report of the committee on a new code. This is the opinion I would form from reading your editorial in the last number of THE NEWS were I not better informed. So far from there being any attempt to "fix" the meeting, I know, as one well acquainted with each member of the committee, and with the Society, that there was no effort of any kind whatever to secure a vote in favor of the new Code, save that made in debate on the floor of the meeting. A resolution abolishing the old Code was introduced by myself without previous consultation with but one member of our Society, and it was passed by a majority of two, as a legitimate result of free debate. Besides all this, the last meeting of the Society, in spite of all statements to the contrary, was well attended from all parts of the State. Whatever the faults and shortcomings of opponents of the Code of Ethics of the American Medical Association may be, they have not yet attempted to stifle discussion or to "fix" delegates.

I am, sir, yours very respectfully,

D. ST. JOHN ROOSA.

NEW YORK, December 16, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 11 TO DECEMBER 18, 1882.

BANISTER, J. M., *Assistant Surgeon.*—To proceed to camp on White River, Colorado, and report to the commanding officer.—*Par. 7, S.O. 250, Department of Missouri, December* 11, 1882.

HALL, W. R., *Assistant Surgeon*—Granted leave of absence for one month.—*Par. 8, S. O. 250, Department of the Missouri, December* 11, 1882.

PORTER, J. Y., *Captain and Assistant Surgeon.*—To proceed to St. Francis' Barracks, St. Augustine, Fla., and to report to the commanding officer of that post for temporary duty.—*Par. 2, S. O. 119 Department of the South, December* 11, 1882.

WYETH, M. C., *First Lieutenant and Assistant Surgeon.*—Granted one month's leave of absence.—*Par. 4, S.O. 206, Department of Dakota, December* 18, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked,

Letters, whether written for publication or private information. must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ON IRITIS.

A Clinical Lecture delivered in the New York Eye and Ear Infirmary, November 23, 1882.

BY RICHARD H. DERBY, M.D.,
SURGEON TO THE INFIRMARY.

(*Specially reported for* THE MEDICAL NEWS.)

GENTLEMEN: The group of patients that I present to you to-day all illustrate in a striking way an affection of the eye to which I desire to call your earnest attention.

In keratitis, scleritis, and other affections, therapeutics are often of very slight value, and whatever is done we often see that, had the course of the disease been left to itself, the result would have been the same. In the treatment of iritis, however, medicine celebrates many a triumph. We shall see that when inflammation of the iris is left to itself, its issue in most cases is very unfavorable; and statistics show that a frequent cause of blindness is a neglected iritis.

Let us, in the briefest way, recall the anatomy of the iris, and we may then consider the pathological appearances and symptoms of this affection, and as tersely as possible describe the methods of treatment at our command.

The *iris* is the anterior portion of the uveal tract. The authors divide it into a pupillary zone which contains the sphincter of the pupil, and a ciliary zone in which the dilator muscle of the iris lies. The epithelial covering of its anterior surface is continuous with that of the membrane of Descemet, the posterior surface of the cornea. The structure of the iris is made up of connective tissue with elastic and muscular fibres. Its nerves are partly sensitive, supplied by the trigeminus, and partly motor, from the branches of the oculomotorius. Its bloodvessels are derived from the long, and the anterior ciliary arteries. The posterior surface is formed of pigmented epithelial cells which are separated from the stroma by a structureless membrane.

The questions which we have to consider in connection with inflammations of the iris are, *first*, What are the signs that we are to look for? *Second*, What are the changes we shall observe in the progress of iritis? *Third*, What are the causes of the inflammation of this membrane? And *fourth*, What treatment is demanded?

Diagnostic signs.—Of the diagnostic symptoms of iritis, perhaps the most important is the blurring of the sight. The patient does not see quite as well with the affected eye as with the other. The aqueous is perhaps a little clouded. In the region of the pupil there may be some exudation, or perhaps there is slight deposit on the posterior wall of the cornea.

In almost all cases of iritis the eyeball is bloodshot very early in the affection. There is a faintly red injection around the margin of the cornea—minute bloodvessels radiating from the cornea appear. This is the so-called ciliary injection, or circumcorneal injection, and once recognized it is not to be mistaken. This injection points always to an inflammation of the cornea, iris or ciliary body.

Another not uncommon symptom of iritis is pain. It may be located in the brow, in the eye, or in the cheek, and be toothache-like in character. In a large percentage of these cases the pain asserts itself at night, when during the day the eye has been quiet.

Looking now at the products of inflammation of the iris we may distinguish, as the authors do, three varieties of iritis:

1. Simple or plastic iritis.
2. Serous iritis.
3. Purulent or parenchymatous iritis.

The *simple iritis* is accompanied by more or less circumcorneal injection. This is sometimes very marked; again so slight that the iritis would escape notice, did we not discover one or two synechiæ or adhesions between the anterior capsule and the iris. There is a slight cloudiness of the aqueous humor, and on covering the well eye we find that the pupil of the eye affected does not promptly respond to the stimulus of light. To confirm the diagnosis now a few drops of a solution of atropine instilled in the eye will show whether or not there are any adhesions between iris and lens capsule. The extent of these adhesions will depend upon the intensity of the inflammation and upon the promptness of the treatment. The margin of the pupil may become entirely adherent to the capsule of the lens, and the existence of these adhesions or synechiæ is a most common cause, as we shall see, of relapse in the iritis.

Serous iritis has been described as a punctate keratitis; inflammation of the membrane of Descemet, and by the earlier writers as an aqua-capsulitis. We have here and there on the posterior wall of the cornea point-like deposits; the anterior chamber is of increased depth; the tension of the eyeball has increased.

The *purulent iritis* or parenchymatous form is characterized by marked swelling and thickening of the iris tissue. The change in its color becomes very marked—almost yellow—and shows many new vessels. Accompanying this there is often an hypopyon; false membranes form in the region of the pupil, and often a subsequent atrophy of the iris tissue is observed.

Let us now look at some of the causes which lead to iritis, and see if there are any diagnostic points which will justify us from the physical signs in assuming the etiology of the disease.

The *syphilitic iritis*, especially when it occurs as a tertiary symptom, shows unmistakable evidence of the disease which lies behind it. Small gummy tumors, more frequently singly, of reddish color, are found on the ciliary or pupillary margin of the iris. When these appearances are present we can safely say that the case is one of syphilitic origin. The iritis which appears early in the course of syphilis, for instance at the period of the roseola, does not so often show these appearances. Graefe found that out of 62 reported cases where these gummata were demonstrable, syphilis could be proved in 60 individuals.

Of the various authors De Wecker especially insists upon certain characteristic appearances of the *rheumatic iritis*. He describes this form as a plastic iritis, associated with marked episcleral inflammation, a loss of transparency of the margin of the cornea; decided sluggishness of the iris and slight exudations upon its surface, robbing it of its brilliancy. Further, this form of iritis is very tedious; it has frequent relapses, leading to the formation of extensive posterior synechiæ, and development of irido-choroiditis.

Iritis may supervene upon gonorrhœa, and in such cases we often note that there is an intervening link in the form of a rheumatic affection of one of the joints.

It is interesting to observe the fact that iritis almost never occurs idiopathically in children. Those of you who have followed the service at the Infirmary of late may recall two children with iritis. In one case the pupil resisted all instillations of atropine; there was a broad synechia upwards and outwards. The intense white reflex which came from behind the plane of the iris pointed to the original affection to which the iritis was merely secondary. It was an intra-ocular tumor, and probably a glioma. Another case was that of a little fellow with pale face and emaciated features. There was malformation of the teeth. The partially cloudy cornea showed an irregular pupil with atrophic iris. This was a kerato-iritis, a manifestation of inherited syphilis.

Syphilis is the cause of 60 to 70 per cent. of all cases of iritis. Of the 30 to 40 per cent. of remaining cases the rheumatic diathesis explains half the number. In a certain number of cases smallpox is a cause, and so are injuries to the eye as well as affections of the cornea.

Let us now consider, gentlemen, the treatment of iritis in general. In no department of ophthalmology has Von Graefe rendered science greater service than in that of diseases of the uveal tract. His clear teachings and wise generalizations have formed the basis of our treatment of disease of this portion of the eye, and to his contributions to this chapter little or nothing has since been added.

Our first principal remedy is atropine. The action of the atropine seems to be a compound one; it exerts a narcotic action upon the ciliary nerves, and it diminishes intraocular pressure. The principal point is the immobility of the iris and dilatation of the pupil which it produces. The iris is put to rest and the accommodation is paralyzed. In the majority of cases the iritis is cured by the atropine alone. Next in value is a pressure bandage, and through this we keep the external musculature of the eye at rest and control the action of the lids. The belladonna and mercury salve that was once so often rubbed upon the brow, never produces mydriasis, and its action is confined to a possible general action of the mercury. Palpation of the eye in iritis is of vast service to us in guiding us to the right treatment. If upon palpation the pain does not increase, there is no indication for local blood-letting. On the other hand, if upon palpation the pain increases, leeches should be applied to the region in front of the ear and not too near the eye. If there is a serous chemosis, it should be incised with the scissors.

Where there is severe pain along the brow, temple, and nose, that does not increase upon palpation, the indication is decidedly against blood-letting. Here opium works admirably, relaxing the sphincter and assisting the atropine. The pain abates, too, under a pressure bandage, and although it cannot always be endured, we should always try it.

Warm compresses or poultices are often of the greatest use—cold applications are always bad, and too often lead to subsequent choroiditis.

When the aqueous humor in cases of iritis is cloudy and the intraocular pressure is increased, paracentesis of the anterior chamber is of the greatest value, and under such circumstances the operation is attended with no danger. The effect of the paracentesis is often beautiful; the pain ceases; the disease changes for the better. In those cases where there is hypopyon, and above it a clear aqueous, paracentesis is not to be thought of. The letting out of the aqueous is followed by hyperæmia of the iris, and the important question naturally is, Is the inflammation of such a character that the hyperæmia can be tolerated? The answer is simple—If the inflammation is serous, the paracentesis is of great service; on the other hand, if the inflammation is plastic, *make no paracentesis*. In plastic inflammations of the iris, the best remedy is mercury—inunction in the axilla, and one-half grain of calomel internally every two hours. With these remedies we usually see in 36 hours an approaching salivation, and here we stop with the mercury. Now comes the satisfactory moment, the plastic exudation goes back, is absorbed. The specific iritis is far less dependent upon changes in the temperature than the simple form, and such cases often are treated as out-patients. In this form mercury must be used. Specific iritis advances irregularly to its acme, and at this point it remains perhaps a fortnight. If the case is well treated, a complication with the inflammation of the choroid is never observed.

ORIGINAL ARTICLES.

IS TUBERCULOSIS A PARASITIC DISEASE?

FIFTH PAPER.

BY GEORGE M. STERNBERG, M.D.,
SURGEON, U. S. A.

FOR reasons given in my last communication to the MEDICAL NEWS, November 18th, I have discontinued, for the present, my experiments with reference to tuberculosis and I do this the more willingly as others have entered the field whose facilities for prosecuting such an investigation are far better than those at my command. I am especially pleased to see that so accomplished a pathologist as Dr. Formad has entered the arena, and that we are not to be left entirely at the mercy of foreign *savants*, even if the National Government, with its enormous revenues, fails to make any provision for scientific work of this character.

If I have not been able to answer the question, *Is tuberculosis a parasitic disease?* the experimental data thus far furnished will at least be of use to the jury—the medical profession—in making up a final verdict; which, I submit, would in the present stage of the investigation be premature. I therefore beg leave to retire from the witness-stand and to take my seat with the jury, with the understanding that I may be recalled if circumstances enable me to add to the testimony already given. First, however, it may be well to make a summary statement of the evidence presented; which I do as follows:

(*a*) The bacillus described by Koch is found in the sputum of phthisical patients in San Francisco.

(*b*) That this bacillus differs from the microorganisms found in normal human saliva and in bronchitic sputum, is proved by the color-test (Ehrlich's) and by culture-experiments (see below, *i* and *j*).

(*c*) Tuberculosis in animals may result from inoculation—subcutaneous—with the sputum of tuberculous patients.

(*d*) But in several of the animals experimented upon, no evidence of tubercular deposit was found, and in others it was very slight. Total number of animals experimented upon, twelve rabbits, two guinea-pigs, and two dogs.

(*e*) In the animals successfully inoculated, the enlarged tuberculous lymphatic glands in the vicinity of the point of inoculation, and tubercular nodules in the lungs and elsewhere, *usually* contained the bacillus of Koch.

(*f*) But this was not invariably the case. At least a careful search failed to demonstrate the presence of this bacillus in tubercles found in the lungs of three rabbits (half-grown white rabbit, killed October 8th, Experiment No. 3; large, spotted rabbit, killed October 7th, Experiment No. 4; small rabbit killed by subcutaneous injection of human saliva, October 6th, Experiment No. 5).

(*g*) The bacillus of Koch was found in abundance in the tubercular nodules from a freshly cut section of human lung, obtained through the courtesy of Prof. Hirschfelder, from the dead-house of the City and County Hospital, San Francisco.

(*h*) But in a similar specimen from another case, repeated examination failed to demonstrate the presence of the bacillus.

(*i*) Culture-experiments have demonstrated that the bacillus in question multiplies upon the surface of sterilized and jellied blood-serum, prepared in the manner described by Koch.

(*j*) But in the writer's experiments the bacilli have not penetrated the culture-medium, or extended upon its surface to such an extent as to indicate that multiplication was at the expense of this jellied blood-serum, which has seemed rather to serve as a *moist*, supporting surface; multiplication has apparently been at the expense of the tubercular material introduced for the purpose of inoculating this culture-medium. The bacilli were not abundant in this material when it was first obtained from the lungs, or from an enlarged lymphatic gland of a rabbit recently killed; but after remaining in the culture-tube for a fortnight the bacilli were found in enormous numbers, while the cellular elements of the tuberculous material had to a great extent disappeared.

TREATMENT OF SHOT FRACTURES AND PENETRATING GUNSHOT WOUNDS OF THE CHEST AND JOINT-CAVITIES BY THE EXPECTANT PLAN, AS WELL AS OF SHOT WOUNDS OF THE SOFT PARTS.

BY H. I. RAYMOND, M.D.,
ASSISTANT SURGEON, U. S. A.

IN THE MEDICAL NEWS of September 23, 1882, among the transactions of the Medical Society of Virginia, is given an abstract of the report of the Committee on Surgery. This abstract relates to drainage in gunshot wounds.

Two of the propositions laid down therein, and several of the conclusions drawn therefrom, are so diametrically opposed to and subversive of the teachings of many eminent authorities, the German school in particular, that a few of the principles in military practice enunciated in that paper should not pass unchallenged. In the discussion that followed the hearing of the report, the argument in part was answered by Dr. R. I. Hicks, who struck the key-note on the treatment of penetrating shot wounds of the chest, but put himself on dangerous and hotly contested ground as to the treatment of penetrating gunshot wounds of the *abdomen*, but failed to observe an erroneous statement in the report made in respect to penetrating gunshot wounds of joints. This will be made mention of later.

Whether this paper was accompanied and supported by illustrative cases, I am not informed, or whether it was constructed upon the statistics of a goodly number of carefully tabulated cases in its author's own experience, or that of other prominent surgeons, I am left only to surmise. Suffice it to say that the exceptional propositions are so startling as to make one question any surgical faith that is in him.

Respecting penetrating gunshot wounds of the chest, I quote from the report: "The cases of penetrating gunshot wounds of the chest which recover, are the cases in which thorough drainage has been practised.

"*No surgeon now thinks of hermetically closing a penetrating wound of the chest.* On the contrary, we are instructed to keep it open. . . . . In empyema great good is accomplished by aspiration, paracentesis, incisions, drainage-tubes, and flushing out the cavity: *and the analogy between the consequences of gunshot wounds and empyema is too striking to be overlooked.*"[1] The question at issue is not whether a purulent collection of matter, or any septic fluid in the body, whether in a gunshot wound of the soft parts, or of the chest cavity, should or should not be hermetically sealed or evacuated; for the principle that septic matters liable to absorption must be gotten rid of at all hazards is, as Dr. Hicks observed, "old as the fathers of medicine."

From the statement in the report that "no surgeon would think of hermetically closing a penetrating gunshot wound of the chest," and that there is "an analogy between the consequences of gunshot wounds of the chest and empyema," the legitimate conclusions that I feel warranted in drawing as intended to be conveyed by the report, are that every, or at least the generality, of penetrating gunshot wounds of the chest lead to the formation of pus or septic fluid, no matter what has been the primary treatment. This principle may pertain to the treatment of gunshot wounds of the *abdomen*, and probably does, as advocated and championed by J. Marion Sims, in his remarks on gunshot wounds of the abdomen in relation to modern peritoneal surgery, as published in the *British Medical Journal;* so that in view of this high authority a surgeon would hesitate to hermetically seal up an abdominal peritoneal wound for fear of septicæmia arising from absorption of the serous transudation within the peritoneum, which fluid seems particularly virulent from osmosis through the intestine, or other cause not pertaining to the character of such fluid when found upon the large absorbing serous surfaces of the knee-joint capsule.

Nor does this blood serum, which is the legitimate result of any gunshot wound, whether in the soft parts or in the closed cavities, appear to be a septic

[1] The italics are mine.

in the abdominal cavity, even when the peritoneum has not been penetrated, but simply bruised, and consequently no ingress afforded to infecting entities from the external world, at least through any wound-track. This has been verified by the four necropsies, now famous, in the military experience of Hunter McGuire, in which the several peritonea were not penetrated, being only bruised by the missiles. In each peritoneal cavity was found a quantity of red serum, and the cause of death in each case septicæmia. But the principle of treatment in gunshot wounds of the abdominal peritoneum is unique and not applicable to wounds of other serous-lined cavities, as, for example, the pericardium, the pleura, or the knee-joint. This is true, inasmuch as it is altogether probable that in gunshot wounds, other than those of the abdominal cavity, the infecting entities rendering the wound or cavity aseptic are introduced from without. In the case of the abdominal peritoneum the rats may be within, and must be gotten out; but in other cases, is it not true the rats are without, and should not be let in?

In wounds of the chest, the bullet itself may prove innocuous, and may have carried no foreign body in with it that may cause septic or purulent infection. This we believe to be the rule, the contrary the exception.

It is manifest, therefore, that the prime factor in treatment of such wounds is to hermetically seal them by antiseptic occlusion, that no infection may take place in a wound non-infected when it comes into the hands of the surgeon. Strange enough, it was the habit in Bellevue Hospital to occlude antiseptically a gunshot wound of the chest, but to probe and introduce drainage-tubes into a gunshot wound of the soft parts. But why should one fear to occlude a bullet wound of the biceps muscle when it is his practice to hermetically seal up a bullet wound of the chest, and that too with good results? Why partiality in the application of the occlusive method to chest wounds and wounds of the joints was not extended to wounds of the soft parts, I cannot account for. It seems that when a joint or the chest-cavity was invaded by a bullet the surgeon did not care to intrude further; forgetful, however, when he came to treat a gunshot wound of the arm, he might there introduce septic matter as easily as into a joint or other cavity. I remember introducing, while interne, a long Nélaton's probe in the case of a pistol-shot wound through the fleshy belly of the biceps for eight inches in the track of the bullet like a scout would follow up an Indian trail. Of course the man got well for all my probing and digital examination and squirting of antiseptic fluids into the track of the wound, all of which measures, while they disinfected their own infection of the wound-track, caused much irritation and swelling, with soreness and stiffness of the arm, for the time being. While junior member on the house staff, I asked one of the house surgeons how I should treat a pistol-shot wound of the cheek in the case of a boy on Second Avenue whom I was called on to attend the evening before, immediately after the accident; whether I should syringe it out with carbolic acid solution and drain, or close up the wound of entrance and exit of the ball. His reply was that in his teaching and experience with gunshot wounds a cylindrical slough commensurate with the area of the wall of the bullet-track, always resulted, and had to be gotten rid of by syringe and drainage-tubes. I therefore syringed it out and kept it open with oakum. The wound in the process of repair became swollen and tender, and had to be frequently poulticed.

Later, since treating such wounds by the simple and effective method of primary antiseptic occlusion, the patients complain of no painful swelling, nor have I seen an indication for a poultice, nor has any symptom of septic infection manifested itself from absorption of cylindrical sloughs, if such have formed in a wound not infected by the surgeon's probe or digit.

But to return to gunshot wounds of the chest; while house-surgeon I gathered the statistics of pistol-shot wounds of the chest occurring in Bellevue during two years, from about June of 1879 to June, 1881.

These numbered ten or more, three of which, being doubtful, were rejected. The rejected cases all recovered. The symptoms of the seven accepted cases were such as to warrant a diagnosis of penetrating gunshot wounds of the chest, viz.: spitting of blood, aspiration of air through the bullet wound, pneumonia, pleurisy, and pericarditis. Each case had one or more of these diagnostic signs of penetration of the chest, pleural cavity, and lung. Of these seven cases one proved fatal. One remarkable recovery was in the case of a Bohemian, a cigar-maker, æt. about twenty years, who, in a fit of despondency over a love affair, thought to put a quietus to his troubles by shooting himself through the heart.

He discharged two barrels of his revolver over the region of the heart, both bullets penetrating the chest walls. On admission into the hospital, frothy blood was oozing from the stoma of the wounds, and the hurried breathing, small pulse, and lividity of the face seemed to betoken impending death. The patient however rallied, and his wounds were dressed by simply cleansing antiseptically their superficies, and occluding their mouths by pledgets of lint, spread with an antiseptic salve, this dressing being held on by adhesive straps.

Pneumonia early set in and pericarditis followed suit. The crepitant râle and pericardial friction sound with increased area of cardiac dulness were made out. The patient recovered. The pericardial effusion was certainly not purulent, nor had we reason to expect that it would be, since no septic matter had been introduced from without.

We do not deny that draining of a *suppurating* pericardium, as done by Rosenstein, is not a proper surgical procedure, but we claim that the pericardial effusion in gunshot wounds is not in the generality of cases purulent or septic, and we have no warrant for anticipating such a probable occurrence by subjecting every case of gunshot wounds of the pericardium to drainage, although, following the teachings of J. Marion Sims, one would be warranted in so doing in gunshot wounds of the abdominal peri-

toneal sac. So much for the expectant plan of treatment in penetrating gunshot wounds of the chest, to which I could add a case in the recent Arizona fight, communicated to the *Medical Record*, and doubtless Dr. Hicks and many other surgeons could contribute to swell the list of such wounds successfully treated by the occlusive method. Do facts then bear out the assertion that "no surgeon now thinks of hermetically closing a penetrating wound of the chest?"

Regarding penetrating gunshot wounds of the joints, the report, after stating that "few surgeons now question the advantage of treating suppuration in joints by free incision, drainage, and antiseptic washes" (which all will admit), it goes on to affirm that "*penetrating gunshot wounds of the joints are invariably attended with suppuration,*"[1] and upon these two premises (the latter of which we do not admit) the author naturally enough comes to the conclusion that penetrating gunshot wounds of the joints should also be treated by free incisions, drainage, and antiseptic washes.

The fallacy lies in the second premise, as most certainly pointed out by twenty-seven tabulated cases in the experience of Karl Reyher, two-thirds of which were treated by primary antiseptic occlusion, and one-third by primary antiseptic drainage; and also by six other cases of the same nature treated by primary occlusion, not even antiseptic. Some of these cases I have made mention of in an article in the *Medical Record*, (Primary Antiseptic Occlusion in Military Practice), but they will serve also to elucidate the fallacy in the second premise above, namely, that penetrating gunshot wounds of the joints are invariably attended with suppuration." Karl Reyher, in the Battle of the Red Cross, had under his care, among the gunshot wounds, twenty-seven penetrating gunshot wounds of the joints, adapted to primary antiseptic treatment. Eighteen of these were treated by primary antiseptic *occlusion*—that is, by hermetically sealing the mouth of the wound by an antiseptic covering without having previously introduced probe, or finger, or drainage-tube into it. Of eighteen such serious joint injuries treated by this method, but one death resulted. The remaining nine cases were treated by primary antiseptic *drainage;* that is by "free incisions, drainage, and antiseptic washes." Of these nine cases of penetrating gunshot injuries of the joints, two deaths resulted.

That is to say, of twice the number of cases of penetrating gunshot injuries of the joints treated by primary antiseptic *occlusion*, but fifty per cent. of deaths resulted as compared with the mortality of half that number of cases treated by primary antiseptic *drainage* as recommended in the report as being the best method of treatment adapted to such wounds.

Add to this result six cases of penetrating gunshot wounds of the joints, treated by primary occlusion, even *not-antiseptic*, in all of which cases there was lodgement of the projectile and recovering with no resulting anchylosis, and in the face of these stern facts, the announcement that penetrating gunshot wounds of the joints are invariably attended with suppuration, is startling.

The report also states that "in gunshot wounds of the extremities we are taught the value of drainage by the good it effects in compound fractures of the extremities."

Now the greatest analogy exists between gunshot wounds of the bones of the extremities and *penetrating* compound fractures of the same from a fall or any injury.

In each case the communication with the external world is slight, and infection may yet be prevented by immediate antiseptic occlusion. At any rate, Prof. Von Bergmann occludes all *penetrating* compound fractures of the extremities, and no longer treats them by disinfection and drainage. Nor does he get septic poisoning, for the reason that he recognizes that what defiles the wound must come from without, and to the anticipation and prevention of the entrance of septic entities, he occludes the wound immediately.

Why not, then, extend the principle of occlusion to gunshot wounds of the extremities, even attended with fracture of the bone?

If there is any merit in the treatment of penetrating gunshot wounds of the chest, or joint-cavities, by the method by occlusion, as I trust is proven by the foregoing statistics, then the following of the eight conclusions drawn by the author of the report on treatment of gunshot wounds must be modified in relation to treatment of shot wounds adapted to primary and antiseptic occlusion as applied by Reyher.

The questionable conclusions of the report are:

1. "What union by primary adhesion is exceedingly exceptional in gunshot wounds?"

2. "What suppuration, granulation, and cicatrization are invariably combined in the process of repair?"

3. "That extensive accumulation and burrowing of pus in a deep, narrow bullet-track, are to be expected and feared."

7. "That by nature's efforts, analogy, and reason, we are taught to think that their more frequent use (incision, dilatation, drainage-tubes, etc.) will lead to better results in this class of injuries."

8. "That the danger incident to their use is far outweighed by the benefit which accrues."

With regard to the primary antiseptic occlusion of gunshot wounds, I feel warranted in postulating:

1. That this method of treatment is applicable to a large percentage of wounds inflicted by a cartridge from a revolver, or cylindro-conoidal bullet from a modern rifle or carbine.

2. That in properly-selected cases, wounds treated by this method do not suppurate or secrete any septic fluid.

3. On the contrary, this immediate antiseptic occlusion is intended to forestall suppuration, to prevent the accession of inflammation, and to allow a reparative reaction and secretion to be set up.

4. That the simplicity of this method should recommend itself to the profession in the treatment of wounds to which it is applicable—although the laity,

[1] The Italics are mine.

to be cured of their leprosy, may seem rather to wish to go on their hands and feet to the river Jordan, than be cured by simple and more effective measures.

MEDICAL PROGRESS.

Syphilitic Organisms.—Further observations of micro-organisms in syphilitic new growths have been published by Birch-Hirschfeld. He has examined a number of recently extirpated condylomata, and also a syphilitic growth in the wall of the heart, and has come to the conclusion that the organisms are not distinct rods or bacilli, as he formerly described them, but merely micrococci, and the appearance of rods is due to the linear association of a number of these elements. It is much more difficult to distinguish the individual elements than in the case of most micrococcal chains, because the organisms in syphilis are not round but oval, so that they are visible, not as points, but as short streaks. In most cases there are both monococci and diplococci; less frequently three or five individuals are united, which curiously simulate long rods with rounded ends. In this the observations of Aufrecht are corroborated. For the demonstration of the organisms in recent preparations, Birch-Hirschfeld prefers potash, by the clearing action of which the micrococci are visible in the tissue on account of their strong refracting power. In a broad condyloma, they lie, for the most part, in small aggregations in the papillæ, and in many of the cells of the adjacent layer of the rete Malpighii. They may readily be detected in the juice of a recently excised condyloma, by tinting in the ordinary way; and of the various tinting agents, Birch-Hirschfeld concludes that fuchsin and gentian-violet are the best. In the growths in internal organs the smallest micrococci are most abundant, and the larger forms seen in the condylomata are seldom met with. In gummatous scars they have been sought for in vain. In more recent gummatous products they were most abundant in parts which had the aspect of growing granulation tissue. They were partly scattered, partly aggregated into groups, which never exceeded a granulation-cell in size; they were also distinctly seen within cells. Many epithelioid cells seemed to have their nuclei filled with these organisms.—*Lancet*, December 2, 1882.

Accidental Diseases of Wounds.—In four recent numbers of the *Wiener Med. Wochenschrift* (Nos. 40, 41, 43, 44) there may be found an excellent contribution on the subject of diseases occurring accidentally in wounds, by Paneth and Rosanes. All the cases of accidental wound-diseases happening in Billroth's clinic during the years 1877-1881 have been collected. By means of numbers and charts the reader is presented with comparative tables of the relative frequency of such affections, and comparisons between the previous and the present series of years have also been instituted. During the last five years Listerism has been in vogue in the clinic, and iodoform has been employed in such cavities as the mouth, vagina, and rectum. We cannot go into the tables and statistics here collated, but must content ourselves with saying that not only has the total number of accidental wound-diseases gradually and increasingly diminished during the years in question, but each disease (erysipelas, pyæmia, septicæmia, and the like) has been less frequent. There seems no reason to doubt that the success has been due to improved hygiene in the local treatment of wounds. We congratulate the authors on the appearance of so useful a piece of work.—*Medical Times and Gazette*, December 2, 1882.

Muscular Hernia.—Dr. Nimier concludes, from an analysis of several cases, that the possibility of the production of hernia of muscular masses is established beyond doubt, but that it is very liable to be confounded with the tumor produced by the rupture of a muscle, or pseudo-muscular hernia; the study of the mode of formation of the tumor, together with the different physical and functional signs, will, however, render a diagnosis possible. The best method of treatment is to form a firm resisting cicatrix in front of the tumor by the action of caustics.—*Arch. Gén. de Méd.*, September, 1882.

Iodoform in Burns.—Dr. A. Selitsky, in *Med. Vestnik*, gives a very detailed history of a complicated case of burns of every degree, aggravated by lacerated wounds, caused by a premature explosion of a charge of powder in a cannon. In this case he used sodium bicarbonate on some of the burns (of all three degrees), and iodoform in others (also of all degrees). The soda was used dry by aspersion; the iodoform in the following two forms:

(1) ℞.—Iodoformi, ... ʒj.
Olei jecoris aselli (morrhuæ), ʒj.—M.

(2) ℞.—Iodoformi. . . . . ʒiij.
Vaseline, ... ʒij.—M.

The old-fashioned Carron oil was also used, in the following form:

(3) ℞.—Amygdal. dulcis olei,
Aquæ calcis, ... āā ʒss.
Acidi carbolici, . . . ʒss.—M.

In every degree of burn the iodoform proved itself far superior to the other remedies. It quickly relieved the pain, redness, and swelling of surrounding parts, drying and healing the wounds, whilst the carbonate of sodium produced a dirty gray, very painful and bleeding surface, which was the last to heal. The pains did not abate at all where the carbonate of sodium was used, but continued for days, when the burns on which iodoform had been used were quite comfortable and healing favorably.—*Physician and Surgeon*, Dec. 1882.

Spontaneous Rupture of the Heart.—Dr. Coupland reports a case of spontaneous rupture of the heart in a man aged sixty, from a sudden fright. He adds the following remarks: Perhaps the fullest information concerning rupture of the heart in literature is that given by Dr. Quain in his Lumleian lectures (*The Lancet*, 1872, i. p. 460), where he states that in 77 out of 100 cases there was fatty degeneration of the heart wall, and that 63 of the patients were above sixty years of age. He also points out what all writers, from Morgagni downwards, have noticed, that the exciting cause of the rupture is some sudden mental excitement or physical effort. In each of these particulars the case above recorded conforms to the general rule, but it may be added that until the day of the attack (which was distinctly referable to a violent mental shock) he had suffered no symptoms pointing to the existence of cardiac disease. Yet the coronary arteries were advanced in calcareous degeneration, and there was considerable adiposity of the heart wall as well as true fatty degeneration. The case also resembles the majority in the lesion being in the left ventricle, but it is somewhat exceptional in the position of the rent, which in most cases has been found in the anterior wall, either in the region of the apex or close to the septum. In this case the rupture, which formed an oblique slit, occurred in the posterior wall at some distance from the septum, and about midway between the apex and base. This localization of the lesion was, no doubt,

determined by the disease of the coronary artery and its branches impairing the nutrition of that part of the wall. The case is further of interest in the prolongation of life after the occurrence of rupture. According to Dr. Quain, "in 71 out of 100 cases . . . . death was sudden, occurring within one or two minutes. One patient, however, lived eight days, 1 six days, 1 three days, 5 lived over forty-eight hours, 3 lived under twenty-four hours, and 19 under twelve hours." In the present case, so complete was the rally under stimulant treatment that the idea of cardiac rupture, at first entertained, was thought to be beyond the mark, and that the case was, after all, one of temporary cardiac inhibition, from the influence of mental agitation. The sudden death, forty hours later, proved the correctness of the original surmise; whilst the discovery at the post-mortem examination of two distinctly separable layers of clot around the heart demonstrated the fact that the rent had been temporarily closed after the first occurrence of hemorrhage. A very important question is here raised; admitting the impossibility of recovery after cardiac rupture, would life have been more prolonged had sedative treatment (as insisted on by writers on the subject) been pursued? This may well be doubted, for although, on *à priori* grounds, it may seem wrong to stimulate to further action the heart so injured, it may equally well be contended that the ventricular contraction would aid in the temporary closure of the rent; whilst on the other hand, continuance of the hemorrhage might be favored by measures tending to prolong the state of diastolic relaxation. In following the indications for prompt stimulation, as the only measure likely to rescue the patient from imminent death, this line of treatment was deliberately adopted in face of the possibility of such a lesion as actually existed. Had stimulants been withheld the man must have died in the first seizure, and in such a case a respite of a few hours may often be of great moment. The inference is that in similar cases—where diagnosis may be even more certain—the natural indication to administer stimulants may not be so harmful as is generally assumed.—*Lancet*, December 2, 1882.

THE ELASTIC LIGATURE IN SOME CASES OF SYMBLEPHARON.—According to MR. SIMEON SNELL, the more complete varieties of symblepharon are best treated, of course, by transplantation of conjunctival flaps. In other instances, where simple bands or bridles pass from the lid to the ocular surface, division of them is sufficient. There are, again, cases which are intermediate between these, and in several such instances he has found the elastic ligature of service. Some of these were cases in which the fold uniting the eyelid to the globe was loose. A needle threaded with a fine piece of elastic was passed deeply through this fold and tied. In two, three, or four days it had cut its way through and come away. In some cases, though not invariably, this simple procedure was certainly of service. He was induced to use it, in the first instance, some years since, by seeing the opinion expressed that the elastic ligature leaves the surfaces cut by it somewhat thickened and less prone to unite.—*Ophthalmic Review*, December, 1882.

TREATMENT OF DIPHTHERIA WITH IODOFORM.—DR. BENZAN (*Wiener Med. Woch.*, Sept. 2, 1882) reports good results from the treatment of diphtheria with iodoform. He applies the iodoform in powder, pure, with a camel's-hair pencil, the patch of membrane to be treated having first been freed from mucus with a douche or with another camel's-hair pencil. He is careful that the iodoform shall cover the whole patch, and yet is equally careful that it shall not be applied in excess so as to be swallowed. The iodoform is applied eight times in the twenty-four hours—six times during the day, at intervals of two hours, and twice during the night. The success of treatment depends upon the efficiency with which these directions are carried out. The author contends that no treatment so effectually suppresses fetor and avoids general septic infection. Six severe cases of diphtheria were successfully treated by him, and he looks forward to better results than he has been able to obtain by other methods.—*New York Medical Journal*, December, 1882.

COMPOUND FRACTURE OF THE LEG; SUTURE OF THE BONE WITH SILVER WIRE.—PROF. KUSTER reports the case of a man, aged 36, who jumped from a height and sustained a compound fracture of the leg above the ankle-joint. A few loose splinters of bone were removed, and the ends of the fractured bone sutured together with silver wire; drainage tubes were inserted, and antiseptic dressings applied. The temperature never became higher than 38.1° C. Cure was complete without any necrosis, in less than four months.—*Med. Chir. Centralb.*, November 24, 1882.

TREPHINING.—DR. OBALINSKI relates in the *Wiener Med. Woch.*, No. 44, two successful cases of trephining. The first occurred in a man, aged forty-five, who, two weeks after a wound of the head, on the left side, showed gradually increasing paralysis of the right side, with augmented knee-phenomenon and some rigidity of muscle. On careful consideration, it was deemed fit to perform the operation of trephining, as it was thought probable that the symptoms mentioned were due to an abscess. The operation was done antiseptically. The dura mater was incised, some yellow matter escaping; the cavity was washed out with a one per cent. solution of thymol, drained, and dressed. Some reaction followed and lasted a few days, but patient's unconsciousness and the bad symptoms soon subsided, and he left the hospital at the end of nine weeks, at the end of which time the paralysis and rigidity had entirely subsided. Dr. Obalinski comments on this case in respect of the disappearance of the paralysis and rigidity. A thorough explanation of such phenomena is very difficult. The case is remarkable in that hemiplegic rigidity of any standing is generally looked upon as indicating sclerosis of the lateral columns. Such a lesion could hardly have been the cause of the increased knee-jerk and rigidity in this case. The second trephining was done for a depressed fracture of the right parietal bone. The patient was a laborer, twenty-five years of age; the symptoms were those usually assigned to compression of the brain. The treatment was again antiseptic, and quite successful, the man being allowed to return to his work in six weeks. The first-mentioned case is the more valuable: in it there was no aphasia; there was some paresis of the right facial muscles, and paralysis of the right arm and leg. If we suppose that there really was, as there seems to have been, an abscess about the convolutions in the neighborhood of the fissure of Rolando, it is remarkable that the paralysis should disappear, but still more so that the signs usually attributed to sclerosis of the crossed pyramidal tract should also fade away. Physiologists and pathologists have long disputed as to how the recovery from paralysis due to cortical lesion can be explained—some supposing that other portions of the same hemisphere can adopt the work of the destroyed convolutions; others holding that the corresponding area of the other hemisphere manages the business. However, no one pretends that we are yet near the goal of our ambition in regard to matters relating to the physiology and pathology of the nervous system.—*Med. Times and Gazette*, December 2, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, DECEMBER 30, 1882.

BACTERIA AND THEIR RELATION TO INFECTIOUS DISEASES.

IN the introductory lecture to his course on medicine, PROF. JACCOUD considered the causation of infectious diseases. He first of all compared the latter with toxic affections. Both are named from an etiological standpoint; both are the result of the action of a substance introduced from without. But in infectious diseases there is something more. It does not follow that because the poison of a given infectious disease is not apparent, it does not exist. We cannot detect the malarial poison in marsh water, and the water of a spring which chemical analysis would indicate to be absolutely pure, may contain the poison of typhoid fever, traceable to a communication with a bed of fecal matter.

As to the nature of the poison, formerly so mysterious, much light has been shed upon it by recent researches on micro-organisms, in the first rank of which M. Jaccoud naturally places those of Pasteur. "The morbid poison," he says, "is in every instance associated with the presence of lower organisms." These are fungi, belonging to the group bacteria, and the class schizomycetes. Of these there are five principal genera: *Genus Micrococcus, G. Bacterium, G. Bacillus, G. Spirillum, and G. Vibrio.* The classification differs slightly from that of Cohn, generally adopted, which includes the *bacillus* and *vibrio* as genera under the class *desmobacteria*, or filamentous bacteria, and the *spirillum* as a genus of the class *spirobacteria.*

But while M. Jaccoud is willing to admit that bacteria play an important *role* in the causation of infectious diseases, he is not willing to admit that they are the exclusive cause. He claims that the liquids in which the bacteria live may also sometimes have infectious properties; nor is he willing to admit that there exists a special form of bacterium for every infectious disease, as some enthusiasts claim. They are known only by their results, not by their morphology, and that which makes a bacterium infectious is its source and not its shape. We are constantly surrounded in health by harmless bacteria which differ from those of diphtheria and variola, for example, only in their origin. But the infectious property, once acquired, is capable of being transmitted from generation to generation, even if artificially cultivated. We are therefore still ignorant of the true nature of the poison, since we are unable to distinguish the ordinary bacterium from the infectious one except by its results. Thus Jaccoud would make the bacterium the contagium-bearer rather than the contagium itself.

It is this point, the indifference of the bacterium *suo ipso*, and its dependence for its activity upon the medium in which it is developed, which would seem to be the distinctive feature of Jaccoud's views as compared with others who admit the significance of bacteria. Thus would be explained the well-known gradual attenuation of the poison in culture experiments, and the results of the experiments of Grawitz, Nägeli, and Buchner. The first of these claims to have communicated to harmless organisms (penicilium, etc.) harmful properties, while Nägeli and Buchner claim to have converted the harmless hay bacillus into the virulent *bacillus anthracis.*

THE TREATMENT OF TAPE-WORM.

OUR eminent pharmacological expert, DR. SQUIBB, in the issue of his *Ephemeris* for November, 1882, offers some practical observations on the "treatment of tape-worm." His conclusion is that an emulsion of pumpkin seeds, and, this failing, the oleoresin of male fern, are as useful as any other remedies; for, as we will presently learn, Dr. Squibb is most concerned in respect to the preparation of the patient, and the mode of administering the remedy. "Under ordinary good management," he maintains, "one parasiticide is about as good as another." His method of preparation consists in fasting and the administration of Seidlitz powders. "After a light dinner, near the middle of the day, the patient should take no food, but may drink freely of water." A Seidlitz powder is administered that evening, and, whether it acts or not, another is given on the following morning, after which the parasiticide is taken. Dr. Squibb's object in the exhibition of the saline laxative, he informs us, is to uncover the worm—to present the head to the action of the tæniafuge. The following is his mode of preparing the pumpkin seeds:

Four ounces must be well beaten in a mortar, half an ounce at a time, a few drops of water being added, until the whole is made into a paste. The shells should be retained, and not separated, as is usually done. The trituration is continued by the addition of water until a pint of emulsion is obtained. This quantity is given in three doses, the necessary quietude and forbearance of the stomach being secured by appropriate treatment. If the emulsion does not purge of itself, a dose of castor oil is given in a half hour after the last quantity, the worm coming away in the evacuation, which should, as Dr. Squibb informs us, be received in a vessel containing water to facilitate the proper examination of the parasite.

If the pumpkin-seed emulsion is rejected by vomiting, or fails to expel the worm, Squibb advises the oleoresin of male fern. The same mode of fasting and exhibition of a saline laxative are directed, after which the fern is administered in scruple doses every fifteen minutes (in capsules) until eight to twelve doses have been taken.

Entertaining the view that the tæniafuges are of equal efficacy, if rightly administered, the differences in result are to be referred to the position of the head. Squibb has observed, he informs us, that the "obstinate cases" are those in which the head is attached so low down in the intestinal canal, and so protected by a coating of tough mucus that the parasiticide does not come in contact with it. This fact, we understand him to say, he has verified on post-mortem examination. As his experience appears to have been gained in the Mediterranean, we are surprised that he does not refer to the difference in the staying power, so to speak, of the armed and unarmed tænia. It is a well-known fact, we believe, that the unarmed variety is very common in the south of Europe, and that tæniafuges which are promptly successful with this class, may be entirely unequal to the dislodgement of the armed tænia (t. solium, for example).

Our estimable and learned *confrère* has nothing to say of other remedies for the expulsion of tapeworm. We are quite disappointed that he does not once refer to Tanret's recent contribution to pharmacology—*pelleterine*, the active constituent of pomegranate, which has proved to be a most efficient remedy. Pumpkin seed and fern are very well, but from Dr. Squibb we expect full information on all sides of a subject. It would have been very gratifying, therefore, if he had gone further into the subject of tæniafuges, and given us exact information in regard to their comparative value.

"THE TYPICAL YANKEE, LANK AND SHRIVELLED."

"ACUTE Americanitis" is the presumably felicitous term by which Mr. Williams, a scientific Englishman, describes in *Knowledge* the effect of our climate on the rotund, not to say obese, inhabitant of the British Islands.

The "lank and shrivelled Yankee" is, from this point of view, merely "a desiccated Englishman." He refers in explanation to the experience of his own son, who came to this country on a scientific expedition, and his letters soon exhibited "a state of abnormal excitement; he grew taller, thinner, lank-jawed, and sallow," and was presently sent home in a "dazed" condition. In other words, this young Englishman was not equal to the demands of the intellectual life into which he was thus suddenly thrown, and fell into a state of confusion, for which the only remedy was a return to the sober, staid, and unvarying conditions of English life. Mr. Williams supports his theory of acute Americanitis, by the experience of Mr. R. A. Proctor. This ingenious vulgarizer of scientific astronomy, on coming to this country expends his energies in popular lectures. Resting in England on the vulgar dollars acquired here, he adds rapidly to his adiposity by the beer and roast-beef of old England. On this side the water, busily occupied, *more Americano*, he consumes no little of the stores accumulated by the good feeding and the solemn repose of his own country. The thirty pounds of adiposity thus consumed is a sacrifice to Mammon, and the American climate is a convenient scapegoat.

Is there any reason to suppose that our American climate is causing a gradual desiccation of rotund John Bull? An attentive examination of the data now at our disposal, must conduct one to the conclusion that truth exists in two propositions:

1. Those recently introduced to the climatic and social conditions of America may consume some extra adipose tissue in the effort to maintain an equal pace with the habitual rate of progress of our citizens.

2. The influence of the American climate on the progeny of Europeans seeking a home here is in the direction of increased bodily development.

The first postulate may be accepted as largely true. "Acute Americanitis"—by which term we mean the effect not only of the climate, but of social conditions of our American life—makes a large demand on the stored-up resources of the human organism. The second proposition involves new considerations. Are there any data, by the application of which we may estimate the influence of our climate on the bodily development and mental vigor of the American race? Observation of the ordinary product of emigrants to this country after three or four generations, and the statistics of the Provost-Marshal-General's Bureau during the late war afford us the necessary data. Any one attentively regarding the descendents of old Puritan, Knickerbocker,

Huguenot, and Creole families, who have been acted on during many generations by the climatic conditions of America, must observe a very marked tendency to fulness of habit, to obesity even. In fact, "the lank and shrivelled Yankee" belongs to that era when the first impressions of the American climate were made on the nutritive functions of European emigrants.

But more conclusive than any mere observation are the statistics of the Provost-Marshal-General, collected under circumstances in which the tendency would be to exaggerate deficiencies of all kinds. These statistics show that the average bodily development of Americans, sprung from European ancestry, is much greater than the ancestral prototype. We may, therefore, reject with a justifiable confidence the fears of our English cousins, lest the lank Yankee prove to be only "a desiccated Englishman." The remedy proposed by Mr. Williams for this melancholy state of affairs is eminently characteristic—that the decaying Yankee return from time to time to his native soil, to procure a fresh supply of the English life-giving principle.

EARTH DRESSING IN GERMANY.

NEUBER, in a report on antiseptic surgery, discusses the various materials available for this purpose, partly from the economic, partly from the efficiency point of view.

Two years ago, he says, he was made acquainted, quite accidentally, with the remarkable antiseptic qualities of earth. A laborer, having suffered a compound complicated fracture of the forearm, induced a comrade to surround his injured parts with a paste of earth mould. On subsequent examination of the arm at the clinic, it was found to be doing admirably, there being not a trace of suppuration, and union took place readily. The result of this observation has been the adoption of earth as an antiseptic dressing at Esmarch's clinic. It is placed in bags of gauze, previously wrung out in a 5 per cent. antiseptic solution, and laid upon the injured surface and retained by a gauze bandage. This dressing has now been applied in a number of cases, with the following results: 133 cases have been so dressed; in 85 per cent. the wound was found to be healed on the removal of the dressing.

Very naturally, the cheapness and efficiency of this treatment has excited high enthusiasm amongst our German colleagues. They will be greatly astonished to learn that they have been anticipated in this discovery, and that Dr. Addinell Hewson, of Philadelphia, had written a volume on the subject long before their untutored rustic presented himself at Esmarch's clinic, healed with an earth dressing.

BRITISH PIRACY AGAIN.

IN one of our earlier numbers for this year we showed the scandalous fraud practised on the British public by Ward & Lock, of London, in the republication of the *American Health Primers* under an English disguise, with the total omission of the names of the authors. We showed also that, though the *Lancet* had been fully informed of the fraud, yet it had never said a word of condemnation.

Such examples we considered to be very exceptional and we confess our surprise in looking over the November number of the *Edinburgh Medical Journal* to find on page 444 a "review" of Baginski's pamphlet on the "Function of the Semicircular Canals," which had a familiar tone, and the more we read of it, the more it seemed not only an echo of our own opinions, but also of our own words. On referring to the MEDICAL NEWS for February 4, 1882, page 140, we found that memory had not misled us. The so-called "review" of our Edinburgh contemporary is our own review *verbatim, et literatim, et punctuatim.* No! we are in error; twice we had it "Menières disease;" twice the *Edinburgh Journal* has "Menière's disease." Scotch air favors accurate orthography. We could wish it were equally favorable to good morals. Fancourt Barnes and Ross need not feel so downhearted, as we fear they did not long since, when this same *Edinburgh Journal* mercilessly exposed their thefts and plagiarisms.

WE regret to have to announce that in the Army Appropriation Bill the Committee on Appropriations of the House of Representatives have reduced the usual annual appropriation for the Army Medical Museum and Library one-half, having allowed only $5,000 for both, instead of $5,000 to each, as has been done for the last ten years. We had hoped that the importance and usefulness of these institutions and the unanimous feeling of the medical profession of the country in their favor had by this time become so well known to Congress that they would be provided for without question. It seems that in this we have been mistaken, and that Mr. Butterworth, of Cincinnati, Ohio, who reported the bill, has, from some motive unknown to us, determined to cripple these interests, and that a majority of the Committee have been so careless as to follow his lead. We sincerely hope that the Senate will correct this blunder, and we advise physicians who have any acquaintances among members of Congress to remonstrate vigorously against this excessively ill-judged attempt at economy.

PILOCARPINE, as our readers are aware, has lately been much vaunted as a remedy for hydrophobia. Some cases have been published in which it seemed

to have curative effects. M. NOCARD, who has especially favorable opportunities for information by reason of his position at the Veterinary College clinic, has recently published a note, giving his conclusions. We need not follow him through his various experiences; it will suffice to state the conclusions to which he is finally conducted:

1. That pilocarpine has neither curative nor prophylactic action in hydrophobia.

2. That it does not effect in enraged animals any modification of the crises which characterize the furious form of the disease.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 28, 1882.

THE PRESIDENT, THOMAS MARKOE, M.D., IN THE CHAIR.

DR. J. C. HUTCHISON read a paper on

SUBCUTANEOUS OSTEOTOMY BELOW THE TROCHANTER.

DR. SANDS referred to a case occurring in an adult, in which he performed Adams's operation. The deformity was anchylosis at an angle of 110°, the result of articular rheumatism. He divided the neck of the femur, and the wound healed by adhesion under a simple dressing. The man was kept in bed for six weeks with a view of obtaining bony anchylosis in a straight position, but a false joint formed, and when he left the hospital, two months after the operation, the limb was shortened one-fourth of an inch. A year and a half after the operation the limb was shortened three-fourths of an inch, and still there was a movable joint, but the deformity was entirely relieved. As in Dr. Hutchison's case, it was necessary to divide some of the tendons in order to bring the limb into the proper position. The final result was that the patient was able, without a cane, to walk with only a slight limp, and with a cane no limp could be detected.

DR. C. T. POORE remarked that he had not seen reported cases in which motion remained after section high up, except in Dr. Sand's and Dr. Sayre's cases, and one published by Dr. David L. Rogers, in 1830, in which motion existed three and a half years after the operation. Barwell, of London, has reported a case in which he performed double section high up, adopting Gant's method, and the patient died on the forty-seventh day from bedsores. The case was one of anchylosis from double strumous hip-joint disease. He thought that osteotomy, as performed by any of the usual methods, could hardly be called subcutaneous.

DR. HUTCHISON thought that Gant's operation was subcutaneous, as the skin was drawn well to one side before the puncture was made. .

DR. POST had performed osteotomy at the upper part of the femur in two cases. In the first, performed many years ago at the New York Hospital, he divided the bone just below the lesser trochanter by an open section. The limb became gangrenous, and the patient died. At the autopsy it was found that the great vessels had become caught over the upper fragment of bone, and in that manner the circulation in the limb had been destroyed. The other case was one in which there had been double morbus coxarius. On a former occasion he had excised the head of the femur upon one side. The head of the femur upon the opposite side subsequently became diseased, and anchylosis occurred while extension was being used. As there was profuse, deep-seated suppuration around the bone, Dr. Post commenced the operation with the view of excising the head of the femur. But, finding that the head was inseparably connected with the acetabulum, he divided the bone with a saw just below the trochanter minor, and as the limb was considerably longer than its fellow, having divided the bone he removed a piece, so as to make the two extremities of nearly the same length. Anchylosis took place after the operation; the limb was in the straight position, and was useful.

DR. HUTCHISON said that one of the most interesting cases he had met with among those reported was Mr. Lund's, of Manchester. There was anchylosis at both hip-joints, the result of rheumatic arthritis. The patient was unable to sit, could only stand or lie down. Mr. Lund performed Adams's operation, and succeeded in getting false joints, after which the patient was able to sit and walk very comfortably. The result was attributed largely to a suggestion made by Mr. Adams that the patient draw up the limb several times a day, while the weight and pulley were attached, for the purpose of preventing union of the bone.

DR. GEORGE A. PETERS directed attention to another method of correcting the deformity, namely, fracture of the bone, which he had regarded as safer than dividing the bone through an open wound. One difficulty, in applying the method, had been to produce the fracture at the exact point desired. This he thought had been overcome by the osteoclast devised by Dr. Fayette Taylor, a complete description of which had been published in the *New York Medical Journal*. In the case reported, Dr. Taylor fractured the femur just below the trochanter, straightened the limb, and Dr. Peters took charge of the case during its progress. The result was complete union with limb in good position. At the time the operation was performed, it seemed to him to be a much safer procedure than section of the bone, and he should be inclined to adopt it.

DR. BRIDDON referred to the case of a girl, 18 years of age, who entered the Presbyterian Hospital with anchylosis at the hip-joint, and anchylosis of the right hand. As he recollected, the heel was five inches from the floor. While making an examination under ether, he accidentally fractured the bone about four inches below the trochanter minor. The limb was placed in the straight position, a fixed apparatus was applied, and union took place. The result was very good. The shortening was very much diminished.

DR. SANDS said he was unable fully to understand how any instrument could determine the point of fracture within half an inch. If it was desired to fracture the bone where it was thickened as the result of inflammation, he should fear that it would give way at its weakest point. In his case the bone was excessively firm, and twenty-five minutes were occupied in dividing it. He was quite certain that the application of a force sufficient to cause fracture would have broken it at some lower point. With regard to the relative safety of osteotomy and fracture, he doubted if there had been sufficient experience to enable us to compare the two operations. Certainly osteotomy had been remarkably successful; and he should apprehend that if force enough was applied to cause fracture, the large bloodvessels might occasionally be injured.

DR. PETERS said, that when Dr. Taylor first proposed the operation he objected to it for the same reasons which had just been given by Dr. Sands; but when he saw the apparatus, and especially after seeing it used, he believed that there was an almost absolute certainty that the bone would not be fractured except at the exact point selected.

The PRESIDENT suggested that fracture at a precise

point, although he had not tried it in the class of cases under consideration, might be secured by first using Brainard's drills, and afterward the osteoclast. He had used the drills in several cases of vicious union with satisfactory results. Another suggestion was with reference to the accident which had occurred in Dr. Post's case. Perhaps the danger had been somewhat overlooked of the sharp edge of bone wounding or abraiding important vessels. This accident had occurred to him—and Dr. Peters would recall the case—after dividing the bone in the middle portion of the femur with great difficulty with a chisel, in a case in which the bone exhibited a deformity nearly at a right angle; after necrosis he had the misfortune to rupture the femoral artery in making extension for the purpose of bringing the fragments of bone into proper position. The result was that the limb was destroyed, although the patient's life was saved by amputation high up. On examination of the limb after amputation, it was found that the artery had become attached to the posterior surface of the bone as the result of long-continued inflammation in connection with the necrosis, and of course when the bone was straightened the artery was torn across. He thought it was one of the points to be borne in mind in all operative procedures in this class of cases.

LITHOLAPAXY THROUGH THE PERINEUM.

DR. GEO. A. PETERS reported a case as follows: On the 6th of November he removed a stone from the bladder of a boy 10 years of age, who had suffered from symptoms of vesical calculus for five years. On examining the bladder with a Thompson's searcher, a stone was readily detected, and it was estimated to be of large size, hard and rough. The patient was prepared for the examination, and after he was placed upon the table, bimanual examination with one finger in the rectum and pressure made above the pubis detected a stone in the bladder, which was then estimated to be an inch in length. Appreciating the fact that he had to deal with a large calculus, Dr. Peters determined to perform the median operation with some modifications, and through the opening thus made in the urethra to crush and remove the fragments. The modification consisted in making the incision through the skin and some distance through the soft parts, and then introducing the knife in the usual manner, touching the groove in the staff, and dividing the urethra. A pair of forceps was then introduced into the bladder, with the expectation of being able to crush the stone; but it was found to be at least one and three-fourths inch in diameter, and the instrument too weak to break it. Considerable difficulty was then experienced in removing the forceps from the stone, as the bladder was empty and had contracted firmly. The forceps being removed, a short lithotrite, which had been made for him by Wiess, of London, for crushing stone in the female bladder was introduced, but after the calculus was grasped it proved to be so large that the instrument could not be locked; Bigelow's large lithotrite was then introduced, the stone secured and crushed several times, several of the large fragments removed with the forceps, and the operation completed with the scoop, passing it over every portion of the bladder. On introducing the finger, he found that the irritation produced by the operation had caused hour-glass contraction, so that there were some fragments shut up in the upper part of the bladder. Finally the bladder was completely emptied; the fragments and detritus collected weighed 470 grains. During the subsequent history of the case nothing of special importance occurred except high temperature—105° F.—during the first part of the twenty-four hours, but that readily yielded, and on the sixth day the boy began to pass water through the penis, and on the twelfth day the urine was passed entirely in the normal manner. From that date the case had progressed favorably.

Dr. Peters suggested that, should he again be called upon to operate in a similar case—a young bladder containing a large stone—he should perform litholapaxy through the perineum in the following manner: Make an incision in the perineum, enter the urethra a little farther forward than in ordinary median lithotrity, and by an incision only large enough to admit a lithotrite, and through that opening crush the stone and evacuate the fragments as in ordinary rapid lithotrity with Bigelow's apparatus.

In connection with the report of this case, DR. PETERS exhibited

AN APPARATUS FOR SECURING GOOD POSITION IN ALL OPERATIONS ON THE PERINEUM, THE BLADDER, THE VAGINA, OR THE RECTUM.

It had been brought from London by Dr. T. A. Emmet, and consisted of two padded rims, rings, or bands to encircle the leg just below the knee; to one ring was attached a steel pad; through the other a barrel which received the rod. The rod could be secured at any point by means of a thumb-screw passing through the wall of the barrel, and thus permitted any degree of extension required (consequently separation of the knees and placing the perineum on the stretch). To the inside of one ring was attached a strap which had to pass around the patient's neck and be held fast with a buckle at the inner side of the opposite ring. With this strap the elevation of the limbs could be regulated.

CANCER OF THE THYROID BODY.

DR. A. G. GERSTER presented a specimen removed last August from a patient 62 years of age. It had the following history: The woman, very fleshy, had carried a goitre for several years. During the last five years she had suffered from periodical attacks of dyspnœa, which passed off without special treatment. For about four months before he saw the patient the dyspnœa had been almost constant, and the general symptoms had increased in severity to an alarming extent. On examination he found in the median line of the neck a tumor about the size of an orange, and hard. It moved up and down with deglutition. The dyspnœa was so marked that the wheezing inspiration of the patient could be heard in the second and third rooms distant. Her face and lips were slightly cyanosed, and she was obliged to maintain the upright position. There was evidence of fatty heart, a certain amount of pulmonary emphysema, apparently induced by the tumor. Several methods of treatment had been employed before he saw the case, and last some sort of injection into the tumor by an irregular practitioner. From that date the alarming condition took its origin. The tumor was attached to the anterior surface of the trachea, and it was evident that tracheotomy, so certainly indicated, could be performed only with great difficulty. One of the two ways could be adopted in performing tracheotomy—either cut directly through the tumor, or remove the tumor first and afterwards open the trachea. He was unable at that time to decide which he would adopt. The patient, however, declined any operative interference and went away. Not long afterward Dr. Post saw the patient and proposed tracheotomy, but the proposition was declined. Finally, Dr. Gerster was called, and was asked to resort to whatever surgical procedure was necessary. Not having a canula of the proper size he was obliged to extemporize one as follows: Three inches and three-quarters of the curved end of a tin catheter of No. 13 English calibre were cut off for a canula. A suitable

piece of sheet-brass was perforated in the middle for the admittance of a canula, which latter also received the two lateral holes near the end fitted to the plate. Two wire loops placed near the large aperture of the plate served to hold the canula and the plate together by means of a wire pin thrust through the loop of the canula.

Although the woman had fatty heart, and her general condition was very bad, he preferred to use chloroform on account of the threatening lung complication. The anæsthetic was administered without accident. An incision extending from the chin to the jugular fossa was made in the median line, and down to the capsule of the tumor. This did not give sufficient space, and a second incision was made at a right angle with the first at about the middle of the neck, and extending from the anterior margin of one sterno-cleido-mastoid muscle to the first incision. Beginning at the lower border of the tumor he proceeded to enucleate the growth, and soon discovered that it was attached to the anterior surface of the trachea. Whenever he lifted the tumor the trachea was so much compressed as to prevent the entrance of air into the lungs. By means of a blunt instrument he therefore dissected the tumor off, and then found that the tracheal rings from the first to the fifth had been involved in the disease. After the trachea had been laid bare there was no diminution in the severity of the dyspnœa. An incision was made through the tracheal rings, and the tube was introduced. No unfavorable symptoms followed. The patient recovered rapidly from the anæsthetic, and took food shortly after the operation. During the first twenty-four hours she had slight fever. In the afternoon of the second day she had an attack of threatening collapse, for which stimulants were given, and she rallied. It was ordered that the stimulants be continued, and increased should threatening symptoms again appear. Either through failure to give sufficient explicit directions or lack of understanding on the part of the attendants, stimulants were given to the extent of producing acute alcoholic intoxication, and on the evening of the third day she was a maniacal drunken person, and in the drunken fit died in collapse.

Dr. Gerster reported the case for its interest in the manner of death equally as much as for the interest in the tumor itself. The tumor had been examined microscopically and determined to be a cancer. Prognosis in malignant growths of the thyroid gland was very unfavorable. In a recent number of Langenbeck's *Archiv*, a synopsis had been given of the published cases, and it had been found that most of the patients perished shortly after an operation, whether for removal of the body or for tracheotomy necessitated by the great difficulty of breathing. But despite the bad prognosis he thought the surgeon was justified in attempting to give the patient relief. The hemorrhage at the operation was very slight, as every portion of connective tissue was divided between two ligatures. In reply to questions, Dr. Gerster remarked that the tracheal rings could not be recognized by sensation as the knife passed through the tissues, and yet the trachea maintained its usual appearance after the tumor had been removed from its anterior surface. In most of the cases similar tumors had existed in the mediastinum, and tracheotomy was therefore performed to obviate death from sudden development of subsequent attacks of dyspnœa.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, December 6, 1882.

The President, W. S. W. Ruschenberger, M.D., in the Chair.

Dr. W. W. Keen, presented a

REPORT UPON A SPECIMEN OF XANTHIC OXIDE CALCULUS,

for Dr. George L. Porter, of Bridgeport, Conn. The specimen consisted of one-half of a stone, an inch and a half long and an inch wide, which is to be deposited in the Museum of the Jefferson Medical College; the other half is in the Army Medical Museum, Washington, D. C.

So rare is this calculus that, including the present specimen, only eight have ever been described, and none of them so completely as Dr. Porter's. Moreover, this is the only specimen ever recognized and described by an American surgeon. Four of the specimens are British, two French, and one German. Marcet in 1817 described the first calculus of this kind which was recognized.

The present stone was passed spontaneously by a woman eighteen years old. Its clinical history presents nothing specially worthy of note, but its chemical constitution makes it very interesting. Xanthine or xanthic oxide is analogous to uric acid, having, however, one less equivalent of oxygen, and is the rarest of all calculi. In the *New England Medical Monthly* for May, 1882, Dr. Porter relates the case in full, with a drawing of the stone, and an analysis and comparison of the eight cases on record and some interesting remarks on xanthic oxide itself.

Dr. John B. Roberts stated that in 1873, Dr. R. J. Levis operated for vesical calculus by lithotrity on a man. The patient, who was aged 69 years, was an inmate of the Pennsylvania Hospital. The fragments were examined by the late Dr. H. B. Hare, the well-known pathological chemist, and found to consist of xanthic oxide. The patient was discharged by request of his friends, while some of the stone still remained in the bladder, and passed from the surgeon's observation.

Dr. James Tyson said that in connection with the case just reported by Dr. Keen, he desired to place on record a case which came under his own observation, of persistent cystin sediment in urine, concurrent with impacted oxalate of lime calculus. G. B. W., a very intelligent physician residing in one of the southern counties of Pennsylvania, and 45 years of age when he first saw him, was lithotomized in Baltimore when he was 28 years old, and a calculus of pure *cystin* removed. From that time he continued, according to his own account, to pass cystin daily. Early in January, 1879, a specimen of urine was sent to Dr. Tyson in which there was considerable pus and a proportionate amount of albumen. In this specimen there was found no cystin, but in later specimens there were found large numbers of the characteristic crystals along with pus and albumen. A little later Dr. Tyson visited him at his home, and found him suffering greatly with extreme lumbar pain, attacks like which he had frequently had before, but the present was one of unusual duration, and had greatly prostrated him. There seemed every reason to believe there was calculus impacted somewhere between the left kidney and the bladder. His sufferings continued, and he was only relieved by death, which occurred on the 6th of March, 1879.

The following notes of the autopsy were received from Dr. Wm. B. Rowland, of Rowlandsville, Md.: The *post-mortem* examination revealed a calculus in the left ureter just ready to pass into the bladder. The

calculus was the size of a large pea, and very rough. Just behind where the calculus was found in the ureter was a collection of pus, dipping down into the pelvis, which would soon have made its exit through the ischiatic foramen if life had been prolonged.

The left kidney was somewhat enlarged, and the right was not more than one-fifth the usual size, but apparently healthy. The bladder, stomach, and bowels were healthy. No mention was made by Dr. Rowland of the liver, which was presumably healthy, but there was found in the gall bladder a calculus an inch long and half an inch in diameter throughout its length.

The calculus, which was exhibited to the College, presented none of the physical and chemical characters of cystic calculi, which are smooth and friable, but is evidently oxalate of lime. This is particularly interesting in view of the fact that a cystin calculus was removed by lithotomy seventeen years earlier, and that the patient so persistently passed cystin crystals up to the time of his death.

THE ANNUAL REPORTS OF THE STANDING COMMITTEES were then presented.

The Publication Committee reported a larger contribution of interesting papers to the forthcoming volume of *Transactions* than has ever been made before.

The Library Committee reported that the library contains 23,653 volumes, of which 15,901 belong to the general library, 6,208 to the "Lewis library," and 1,544 are duplicates. During the year 1882, the additions to the library amounted to 1,234 volumes. A complete card catalogue of authors and subjects has been made of the "Lewis library," and that of the general library is well advanced. The library of the late Dr. H. Lenox Hodge, containing 1665 volumes, is deposited with the College in trust. The constant and rapid growth of the library obliged the committee to urge a liberal appropriation for the extension of the shelfroom and the payment of the librarian and the assistant charged with preparing the catalogue. Next to the Library of the Surgeon-General's office, that of the College of Physicians of Philadelphia is the largest medical library in the United States.

The Mütter Museum Committee urged the necessity of providing increased accommodation for the museum.

During the last year a large number of valuable preparations have been received:

From Framond, of Paris, 100 wax specimens illustrating diseases of the eye; 22 preparations (natural) showing dentition from early life to old age; 20 casts of female pelves taken from noted cases of deformity; 1 large wax model of thoracic duct and lymphatics; 2 rubber models of pelvic viscera, male and female; 1 wax preparation of confluent smallpox; 1 wax preparation of syphilitic disease of scalp; 4 natural lymphatic injections of foot, hand, and stomach, also an injection of the canal of Fontana; and 1 adult skeleton, mounted at Royal College of Surgeons, London.

They have also received from Rohon, of Vienna, six mounted skeletons, illustrating stages in development, with known age and history to each.

They have procured and had mounted the skeleton of a noted case of hydrocephalus.

Also through Dr. Hays, the Committee obtained the body of a cyclops which was dissected, and reported upon by Drs. R. Meade Smith and A. J. Parker (see *The American Journal of the Medical Sciences* for July, 1882). A good plaster cast and two drawings were made from it. Other preparations of importance were also received.

The Committee on the Directory for Nurses reported that the Directory was opened May 15, 1882. Rooms for the secretary were fitted up, and the telephone and telegraph introduced. Circulars and blanks to the number of 8,500 were prepared and widely distributed to all the physicians in Pennsylvania, New Jersey, and Delaware, and to the summer hotels within easy reach of this city. The coöperation of the two training-schools for nurses (the oldest two in the country) was secured, and the medical and daily press of the city showed a very friendly spirit, and assisted us in making the Directory known. The following are the rates of charge adopted: For information leading to the engagement of a nurse between 7 A. M. and 6 P. M., one dollar; between 6 P. M. and 10 P. M., two dollars; between 10 P. M. and 6 A. M., three dollars; for wet nurses, uncertified, five dollars; for wet nurses, certified (after careful medical examination of mother and child), ten dollars; for finding and sending a nurse, an additional dollar. Up to December 1, the number of applications for registration has been 296. Fully registered, 214; approved and awaiting registration, 17; disapproved, 19; stricken from roll for grave faults or defects, 2. Of the registered nurses there are 26 males and 187 females; 35 graduates of training-schools; 165 non-graduates; manipulators, male and female, 11; cuppers and leechers, 3.

The number of calls for nurses has been 342 during the seven months, an average of about 50 a month. We have furnished as many as 8 in a day, and 5 to a single family. One of the most important results achieved through the Directory is the promptness with which calls to grave emergencies are met. Another and very marked advantage of the Directory is, that we not only give information as to disengaged nurses, but, if desired, will find and send them to the patient. This saving of time and trouble to applicants is often very desirable, and the small extra fee charged for the service (one dollar) is very gladly paid. Especially is this service valuable to patients out of the city.

We have also undertaken to supply wet-nurses. We have had 35 applications, but have only been able to supply 13, and we beg especial attention to this fact, in order to obtain many more of this class of nurses.

Our expenses have exceeded our income by a very large amount, and had it not been for the generous contributions of many friends, chiefly through Mrs. Weir Mitchell, the Directory could not have been placed on a firm foundation at its start. Next year it is hoped that it will be about self-supporting.

CORRESPONDENCE.

COLOR-BLINDNESS IN THE RAILWAY AND MARINE SERVICE.

To the Editor of THE MEDICAL NEWS.

SIR: In your number of December 2d, page 644, you state that Sweden refuses to allow a color-blind railroad employé or sailor to be in service. The edicts from the King of Sweden, of July 17th, to go in force January 1, 1883, may be found in the *Railway Review*, of Chicago, of October 21st. The edict as to the railroads says, that no one shall be employed without a proper certificate from a competent physician, duly authorized, as to freedom from color-blindness.

Quite different as to sailors. The King, in the edict, in reply to the request of the Chamber of Commerce asking for a control of the color-sense of seamen, says, "Since, however, the purpose of such edict cannot be gained on seas navigated by foreign ships unless the color-blind are as well forbidden to man these, and as the governments of the principal maritime nations have as yet come to no international agreement as to the control of the color-sense, we have for the present, and until such agreement is come to, not found reason to absolutely forbid the employment on board Swedish

ships of seamen lacking a normal color-sense, but decided that the law in this matter shall be confined to a proscription requiring anybody desiring to ship in a shipping-office to procure a certificate as to his color-sense, by which ship-owners and masters may be enabled to avoid employing the color-blind in duties requiring the distinguishing color signals. Pending this, we have to-day issued a proper edict, hereby communicated to you."—Stockholm, July 17, 1882.

It will be seen that Sweden as well as the other European countries awaits the action of the present Congress, before whom is a bill authorizing the President to initiate an international commission. The same bill was reported, but not acted on, by the previous congress. It can be brought up and carried through by the naval committee if the public press will assist in calling for it, and spreading a knowledge of the circumstances through the several communities of the country. I remain,

Respectfully yours,
B. JOY JEFFRIES, M.D.

BOSTON, December 12, 1882.

A CARD FROM WM. R. WARNER & CO.

To the Editor of THE MEDICAL NEWS.

SIR: The article in the last number of THE MEDICAL NEWS on the Analysis of Quinine Pills does us great injustice. Our house and products have been known to the medical profession for a quarter of a century, and no guarantee is needed as to our intention and desire for the superiority of our preparations.

It is claimed by eminent chemists that the analysis of quinine, particularly when presented in the form of pills, is very unsatisfactory and uncertain, and we must conclude that there is as much liability of error on the part of the analyst as on our part in making up these pills. Had we been given a hearing in the matter before the article was published, we could have satisfied you and through you assured the profession of our care and accuracy.

Respectfully,
WILLIAM R. WARNER & CO.

PHILADELPHIA, 12, 22, '82.

To whom it may concern:

The recipe for making two (2) grain quinine pills is copied in a book kept for the purpose; said book being in my custody and under my supervision as Superintendent of the Laboratory Department of William R. Warner & Co., and that said recipe is so proportioned that each pill should contain the full amount of material as expressed on the labels, and that each working slip is copied from said book as above.

And further: That in each instance a full quantity of material (quiniæ sulph.) is furnished to the person who manipulates the mass, for each lot of said pills ordered to be made.

And further: That it has always been the intention of the subscriber, acting for the said Wm. R. Warner & Co., that the said pills should be correct in composition and weight.

FRANK M. RAMSEY.

Sworn and subscribed before me this 23d day of December, A. D. 1882. } FRANK M. RAMSEY.
W. W. DOUGHERTY,
[L. S.] *Notary Public.*

I superintend and assist in the making of all quinine pill masses in the manufactory of Messrs. Wm. R. Warner & Co.

The recipes are so constructed as to yield definite results, and I always receive the full quantity of quinine for each lot of pills to be made.

I have never been dictated to nor influenced by any one in any manner to make short weight or adulterate quinine entering into pills.

These pills have always been made as accurate as my skill and good intentions could suggest.

GEORGE A. HAFFA.

Sworn and subscribed before me this 23d day of December, A.D. 1882. } GEORGE A. HAFFA.
W. W. DOUGHERTY,
[L. S.] *Notary Public.*

NEWS ITEMS.

NEW YORK.

(*From our Special Correspondent.*)

HEAVY DAMAGES AGAINST THE CITY.—Martin Lighott recently brought suit against the city for $25,000 for injuries received, his wagon having run into a large hole in the street. Drs. Janeway and Sayre testified that the resulting trouble was Pott's disease, and Drs. Allan M. Hamilton, Meredith Clymer, W. A. Hammond, and L. A. Stimson held that the patient suffered from sclerosis of the cord due to cold and exposure. The jury considered that the man's condition arose directly from circumstances connected with the injury, and gave him the full amount. This is the largest verdict ever obtained by any individual who has sued for damages.

LIBERATION OF INSANE PATIENTS.—Much excitement has grown out of the liberation of six or eight patients from the Ward's Island Asylum. There can be no doubt of their insanity, judging from the facts, and we may expect, as a result, a wife-murder or two, and several suicides.

The newspapers, as usual, appealed to the feverish and unreasonable sentimentality of the public, and several so-called "experts," who usually hang about the courts, were found who were ready to "testify." One of these solons satisfied himself of the plaintiff's insanity by asking him "whether he had any delusions," and upon the denial of the patient the matter was settled—at least in his mind.

The sympathy of the respectable portion of the profession is with Dr. A. E. MacDonald, the Superintendent of the Ward's Island Asylum, who has suffered from the interference not only of the shyster lawyers who have invaded his asylum, but of the impertinent meddling of various visiting boards, which, as usually found, are composed of idle and eccentric reformers, silly simple women of uncertain age, with irritable ovaries and hysterical tendencies, and fussy nobodies.

PRACTISING WITHOUT LICENSE.—"Dr." Franz E. Ruhnberg was arraigned for practising medicine without having registered under the State law of 1881, governing the licensing of physicians. He pleaded guilty and was fined $250.

THE COLLECTIONS OF THE HOSPITAL SATURDAY AND SUNDAY ASSOCIATION in three years have amounted to $113,000. There are seventeen hospitals affiliated with the Association, and in the past year they have given free treatment to 6,945 patients. Auxiliary societies are forming; the dry goods trade have organized one, and the Stock Exchange proposes to form another. A contributor of $10 or more, annually, will be considered a member and be entitled to nominate a patient for free hospital treatment.

A NEW WEEKLY.—The lunatics at the Ward's Island Asylum are about to publish, next January, a weekly newspaper called *The Moon*. They will write all the "copy," set the type, and print the paper. There are

a large number of practical printers among the inmates of the asylum. Its printing office has a fine press run by steam, and a lever press for job work. All the printing of the Department of Charities is done in this office.

CATSKILL, N. Y.

(*From our Special Correspondent.*)

The Medical Society of the County of Green (N. Y.) and the New Code.—The Medical Society of the County of Green, at its stated meeting held December 12th, voted down a resolution expressing approval of the New Code.

BOSTON.

(*From our Special Correspondent.*)

Dr. Carpenter on Human Automatism.—*The fourth lecture* treated of automatism of the intellect, the subject being introduced by the statement that when we *will*, it is not the muscular movements and combinations by which results are effected that we will, but the results themselves. The eye is moved by four direct and two oblique muscles. When we will to raise or lower the eyes, corresponding muscles are called into play in each orbit, but when we will to turn them from side to side, the inner muscle of one eye acts in unison with the outer muscle of the other, a fact which leaves no trace upon the consciousness. Again, if we will to fix the eyes upon some object, and at the same time will to turn the head from side to side, the ocular muscles perform automatically the motions requisite to preserve the fixed gaze of the eyes. The oblique muscles are still more demonstrably automatic, for not only is there no conscious direction of them by the will, but even their use was unknown until Helmholtz explained it.

Some light is thrown upon acquired automatism by misspelling or the use of wrong words in the automatism of writing. In this it usually chances that the letter or word is simply out of place, being one which is coming later in the sentence, but is prematurely grasped by the automatism.

Acquired automatisms indicate the formation of new nerve structures in the nervous system and whose tendency is to become hereditary. This is especially true of automatisms formed early in life, when large additions to the system are being made, and these under the influence of habit readily take certain forms which, once acquired, incline to perpetuate themselves. Habits formed in maturer life are more difficult of acquisition and fade out more rapidly, as is shown in the experience of every musician, who knows that daily practice is necessary to keep his automatism in working order.

A purely intellectual automatism is the probable inexplicable process whereby we refer a sensation—which is wholly a subjective phenomenon, its real seat, therefore, being within the cerebrum—to the localities in the body in which reside the terminal fibres of sensory nerves. If the nervous tract be shortened, as in amputation, or if the nerve be unusually excited at some intermediate point, the sensation is nevertheless mentally referred to the normal end of the nerve. The well-known illustrations of pain or coldness in the foot or hand of amputated limbs were used in proof. A slight electric shock to the inner fibre of the optic nerve will give a sensation of light, no change having been experienced by the retina. Sensations are suggested by mental conditions—*e.g.*, the sight of a heaving sea often causes seasickness. The model of a ship when caused to pitch and roll in imitation of a real ship, frequently produces the same result.

An old physician has recorded that the appearance of the decomposing body of a dog caused him to vomit, and that years after merely the sight of the place where the dog had been seen produced a repetition of the experience. The explanation is that the optic nerve conveys the impression it receives to the ganglionic tract at the base of the skull, whence it is sent to the cerebrum, where it is compared with other impressions supplied by memory, the result being a message to the muscles concerned in emesis, the whole being automatic. Spectral illusions, visual presentations of numerals, etc., are to be similarly explained.

The influence of concentration of attention upon selected impressions is to exalt in an astonishing degree the range and accuracy of the perceptions upon which the attention is fixed. Laura Bridgman has been known to recognize, after a lapse of twelve months, a comparative stranger by a clasp of the hand. That this in the main is due to the exclusive direction of the attention to certain senses and not to a sharpening of the senses themselves, as is commonly supposed, seems to be proved by the experiments of Dr. Bray, of Manchester, England, upon cases of artificial sonambulism. One patient exhibited remarkable exaltation of the sense of touch and the muscular sense, so that, while unable to see, he would write easily, with proper spacing of words and lines, returning at the end of a line to dot the i's and cross the t's. Others experienced intensification of the sense of smell, to the degree of being able by means of that sense to detect in a large audience the owner of a glove or ring which had been given them.

A noteworthy illustration of the subject is our power of distracting the attention from one sensory impression in order to fix it upon another. For example, Sir Walter Scott dictated the whole of "The Bride of Lammermoor" while suffering from an acute disease, and experienced no pain while his mind was engaged in literary composition. Curiously, on his recovery, Scott had no recollection whatever of the book he had composed. While preaching, Robert Hall was insensible to the pangs of a terrible disease which caused him to roll on the floor in agony at the close of the service. During his final illness, Dr. Edward H. Clarke, of Boston, suffered excruciating pain, to which, however, he could at will become indifferent by concentrating his thought upon the book he was preparing. The physiological explanation of these phenomena is that the fixation of attention determines the quantity of blood supplied to a given sensory apparatus and thereby limits its activity.

Another intellectual automatism is that which enables us to recognize the "outlines," or objective reality of the causes of a sensation. Sensation, as Berkeley taught, is really a subjective phenomenon, and is referred to outward objects by an automatic combination of concurrent experiences, all of which tend to bring us to this opinion. The test which enables us to distinguish between dreams and reality, is that in dreams one or more of these concurrent experiences are inconsistent with the rest. Dreams which we are hardly able to distinguish from reality are so simple that their concurrent experiences are coherent, *i. e.*, they might really have occurred.

This automatic integration of a number of individual experiences, and the manner in which it deceives us when unusual combinations are presented, was illustrated as follows: Two sheets of paper, the top and bottom of each shaped by arcs of concentric circles, and the ends bounded by the radii, were placed one above the other on the blackboard, the audience being asked to observe that the lower one appeared the larger. Being transposed, the lower still appeared the larger, although they were alike in size, the seeming difference being a deception due to the automatic conclusion that the radii of the two papers are concentric.

CHARLESTON.

(From our Special Correspondent.)

THE EPIDEMIC OF BREAKBONE FEVER which had prevailed here has disappeared completely with the presence of ice. This shows its relation to yellow fever.

MONTREAL.

(From our Special Correspondent.)

RARE SEQUEL OF FRACTURE OF THE BASIS CRANII.—At the last meeting of the Medico-Chirurgical Society of Montreal, a specimen was shown in which the right carotid artery in the cavernous sinus had been opened by ulceration from the sphenoidal cells, with the result of fatal hemorrhage from the nostrils. The young man had received a severe wound over the right eye by the explosion of a boiler, six weeks before his death. After recovery from the shock there were no cerebral symptoms, and the wound healed well. The sight of the right eye failed, and Dr. Bullard recognized a commencing atrophy of the optic nerve, and attributed it to extravasation in the sheath. He had several attacks of bleeding at the nose, but his general health was good. Suddenly one morning, while washing his face, profuse hemorrhage took place from the nostrils, and death followed before assistance could be obtained. At the autopsy the body and the right lesser wing of the sphenoid were eroded and soft, and a line of erosion extended beneath the dura mater along the right orbital plate of the frontal bone. Just where the carotid turns up to become the middle cerebral and where it lies in close apposition to the thin wall of the sphenoidal cells a perforation, 3 x 2 mm., had taken place.

There had doubtless been a fracture of the sphenoid at the time of the injury with subsequent ulceration of the bone.

KINGSTON MEDICAL SCHOOL.—The difficulties at this school, referred to in our last number, have been settled by the faculty agreeing to give separate courses to the lady students.

VIENNA.

(From our Special Correspondent.)

STATISTICS OF THE VIENNA GENERAL HOSPITAL.—The official report of the Vienna General Hospital for 1881, has recently been made public. A few of the carefully compiled statistics of Obersanitäts-Rath Dr. Hofman are quoted here.

Number of patients treated in 1881, 23,565; number of patients discharged, 12,268; cured, 3866; improved, 2353; not cured, 3007; dead, 13.7 per cent. (with exclusion of tuberculosis, 9.1 per cent.).

The number of sick in 1881 shows an increase of 316 above that of the previous year; number of dead, an increase of 107; a mortality increase of 0.3 per cent.

Number of sick with tuberculosis of lungs was 2034, of whom 1195 died, 777 were improved, and 62 unimproved.

Mortality in ileo-typhus in 212 cases was 22.6 per cent. Mortality in exanthemata-typhus in 52 cases was 23 per cent.

Tracheotomy was performed 30 times, with 4 perfect recoveries, two in which results are uncertain, and 24 deaths.

Herniotomy was performed 59 times, with 22 deaths.

Lithotripsy was performed 14 times, with one death; this patient had the operation repeated.

Litholapaxy was performed 22 times, with no deaths.

Laparotomy was performed 20 times, with 13 deaths, and 5 perfect recoveries.

Ovariotomy was performed 64 times, with 38 complete recoveries, 25 deaths, and one woman was discharged with marasmus.

Total extirpation of the uterus was performed 6 times, with 3 recoveries and 3 deaths.

SMALLPOX.—The whaling bark Hercules arrived at New Bedford, on the 24th. She has had ten cases of smallpox on board, three of which proved fatal. Those who died were foreigners.

CARELESSNESS WITH CHLOROFORM.—The Marine Court of New York was lately called to decide a lawsuit against a dentist of that city for a careless use of an anæsthetic, and it laid down a slightly stricter rule than that of some former decisions. The story of the case was that a patient applied to take laughing gas and have a tooth extracted. The gas was administered and the tooth was pulled; but at the critical instant the forceps slipped and a part of the tooth dropped down the patient's throat, lodging in the bronchial tubes. It took the man a month to cough it up, during which time he suffered severely. The jury found that there had been some negligence, and awarded $500 damages, which the Court confirmed, saying that as an anæsthetic deprives a patient of the control of his faculties and renders him unable to take any precautions or make any efforts for his own safety, the physician or surgeon administering it must exercise the highest professional skill and diligence to avoid every possible danger. The professional man, no matter how skilful, who leaves an essential link wanting or a danger unguarded in such treatment, is chargeable with negligence, and answerable for any resulting ill consequences.

Lawsuits of this nature have been very rare. In a New Jersey trial of a dentist for manslaughter, where one of his patients had died under the administration of chloroform, and there was some evidence that the dentist did not use proper precautions and that he was somewhat intoxicated at the time, the judge told the jury that practitioners are only expected to exercise ordinary skill and are not responsible for a death merely because unusual skill might have prevented it. In a Pennsylvania case the patient had previously had a severe fall which rendered him liable to paralysis, and he was, therefore, not a fit subject for an anæsthetic. The dentist, not knowing this peculiarity, gave an ordinary dose of chloroform, and finding this ineffective, gave more, until at length the expected effect was produced, and the obnoxious teeth were extracted. But next day the patient had an attack of paralysis, which his physicians attributed to the overdose of chloroform; and he sued the dentist. But the Court said that a practitioner is not responsible for remote or unknown causes of injury or for peculiarities of personal history or condition which are not explained to him; but if chloroform is ordinarily proper to be given in like cases, a dentist is justified in giving it. Some esteemed legal writers, however, say that a doctor ought to make examination and inquiry before he administers these dangerous agents.—*N. Y. Tribune.*

CONGRESSIONAL APPROPRIATION TO KEEP OUT EPIDEMIC DISEASES.—The Select Committee on epidemic diseases has asked, through Senator Conger, an appropriation of $25,000 to enable the National Board of Health efficiently to coöperate with State and other Boards of Health, in quarantining and examining immigrants for the remainder of the current fiscal year, in order to prevent the introduction and spread of smallpox and other infectious diseases. A bill for this purpose was reported by Mr. Conger to the Senate.

NEW GOVERNMENT HOSPITAL AT HOT SPRINGS, ARKANSAS.—A space in the southwest corner of the Government reservation at Hot Springs, Arkansas, has been selected as the site of the new Army and Navy Hospital for which there is an appropriation of $100,000. The matter is in the hands of the Surgeons-General of the Army and the Navy, who are now engaged in preparing the plans and specifications of the building.

DIPHTHERIA IN ST. PETERSBURG.—According to Dr. Gonz, in the *St. Petersburg Gazette* of December 3d, diphtheria has been very prevalent and fatal during the present year, the mortality being 47.1 per cent.

A comparison of the records for the past five years shows the recent fatality of the disease:

In 1877	the deaths	from	diphtheria	were	206
" 1878	"	"	"	"	508
" 1879	"	"	"	"	362
" 1880	"	"	"	"	355
" 1881	"	"	"	"	708
" 1882	(10 months only)			"	1066

A NEW JOURNAL DEVOTED TO SANITARY INTERESTS.—A new journal devoted to the interests of sanitary science, entitled *The Sanitary News*, is to be published semi-monthly, in Chicago.

WAYNFLETE PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF OXFORD.—DR. JOHN BURDON-SANDERSON, F.R.S., Jodrell Professor of Physiology in University College, London, has been elected Waynflete Professor of Physiology in the University of Oxford.

PRESENTATION TO M. DUMAS.—On Dec. 6th, the French Academy celebrated the occasion of the fiftieth anniversary of the election of M. J. B. Dumas, the celebrated chemist, by the presentation to him of a handsome bronze medal. M. Dumas is in his eighty third year, and has been perpetual secretary since 1868.

THE DUBREUIL PRIZE.—The Medical and Surgical Society of Bordeaux announce the following as the subject for 1883: "The Value of the Antiseptic Method in the Prophylaxis and Treatment of Puerperal Affections." The memoirs should be addressed to Dr. Donaud, Allées de Tourny, No. 10, Bordeaux, and should be sent before Aug. 10, 1883.

PROF. VIRCHOW'S HEALTH continues to improve, although, on November 26, he had a slight relapse from exposure in going to the Pathological Institute.

M. GAMBETTA'S WOUND.—The Paris correspondent of *The Lancet* writes: On Monday morning, about eleven o'clock, M. Gambetta met with an accident at his country house at Ville d'Arzay, a small town just outside Paris, under the following circumstances. M. Gambetta fired off a revolver in his bedroom, and, forgetting that another barrel was still loaded, held it with his hand over the muzzle, when it went off, the ball entering the palm of the hand and making its exit about the middle of the forearm. The doctor of the place was immediately sent for, and the wound was dressed by him. Meantime, Dr. Lannelongue, hospital surgeon, was summoned to the patient from Paris, and arrived about two hours after, when he examined the wounds superficially, and dressed them temporarily with the intention of re-examining them more minutely the next day, which he did, and declared that there was no fracture, no artery wounded, and that he did not anticipate any complication, notwithstanding the fever which had declared itself, owing to which the patient was obliged to take to his bed. Dr. Lannelongue reports that the patient's condition is as satisfactory as possible, and that the fever has entirely subsided.—*Lancet*, December 2, 1882.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending Dec. 16, 1882, indicate that typho-malarial fever, pneumonia, tonsillitis, bronchitis, and whooping-cough have increased, and that remittent fever has considerably decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending Dec. 16, and since, at 17 places, scarlet fever at 16 places, and measles at 3 places. The last case of smallpox, at Grand Rapids, was discharged from hospital Dec. 14.

OBITUARY RECORD.—A cable dispatch of the 25th inst. announces the death in Paris of Dr. Corvisart, the eminent French physician. It is stated that he never recovered from the shock he received at the announcement of the tragic death of the Prince Imperial in Zululand.

NOTES AND QUERIES.

CORRIGENDUM.

IN our issue of the 16th inst., page 689, the formula for crystallized bisulphate of quinine, $C_{20}H_{24}N_2O_2$, $H_2SO_4+7H_2O$, was incorrectly printed $(C_{20}H_{24}N_2O_2)_2H_2SO_4+7H_2O$. The formula was correctly written in the manuscript copy, and the error is typographical.

AN ENGLISH TRIBUTE TO DR. HOLMES.

Punch pays the following graceful tribute to Dr. Holmes:

"Sweet Holmes!

"(Dr. Oliver Wendell Holmes has resigned the Chair of Anatomy at Harvard University.)

"Your health, dear 'autocrat!' All England owns
"Your instrument's the lyre, and not 'the bones;'
"Yet hear our wishes—trust us they're not cold ones!
"That, though you give up bones, you may make old ones."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 18 TO DECEMBER 25, 1882.

ALDEN, CHARLES H., *Major and Surgeon.*—Now in St. Paul, Minn., to proceed to Fort Yates, Dakota Territory, and report to the commanding officer of that post for duty.—*Par. 3, S. O. 212, Department of Dakota, December* 14, 1882.

BROWN, JUSTUS M., *Major and Surgeon.*—Granted leave of absence for fifteen days.—*S. O. 119, Department of the South, December* 11, 1882.

BANISTER, J. M., *Assistant Surgeon.*—To proceed to camp on White River, Colorado, and report to the commanding officer for duty.—*Par. 7, S. O. 250, Department of the Missouri, December* 11, 1882.

HALL, W. R., *Assistant Surgeon.*—Leave of absence for one month is granted.—*Par. 8, S. O. 250, Department of the Missouri, December* 11, 1882.

MADDOX, T. F. C., *Assistant Surgeon.*—To report to the commanding officer at Fort Clark, Texas, for duty.—*S. O. 138, Department of Texas, December* 16, 1882.

PORTER, J. Y., *Captain and Assistant Surgeon.*—To proceed to St. Francis' Barracks, St. Augustine, Fla., and to report to the commanding officer of that post for temporary duty.—*Par. 2, S. O. 119, Department of the South, December* 11, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*
